FACTORS FOR CONVERTING ENGLISH UNITS TO INTERNATIONAL
SYSTEM (SI) UNITS

The International System of Units is being adopted for use in reports prepared by the U.S. Geological Survey. To assist readers of this report in understanding and adapting to the new system, many of the measurements reported herein are given in both units. Chemical data for concentrations are given only in milligrams per liter (mg/L) or micrograms per liter ($\mu\text{g}/\text{L}$) because these values are (within the range of values presented) numerically equal to equivalent values expressed in parts per million, or parts per billion, respectively.

Multiply English Units	By	To Obtain SI Units

WATER RESOURCES OF THE WEISER RIVER BASIN,

WEST-CENTRAL IDAHO

By

H. W. Young, W. A. Harenberg,

and Harold R. Seitz

ABSTRACT

The study area comprises about 1,600 square miles (4,100 square kilometers) in west-central Idaho and includes the entire Weiser River basin and small areas both west and south of Weiser outside the basin. The basin is sparsely populated and the economy is chiefly agricultural.

The principal use of water in the basin is for irrigation, and the largest source of readily available water is surface water.

The principal aquifers in the basin are in the basalt of the Columbia River Basalt Group and the overlying Tertiary and Quaternary sedimentary rocks. Ground water occurs under artesian and water-table conditions in both types of aquifers.

Reported well yields in the basin range from 1 to 1,83⁵ gallons per minute (0.063 to 122 liters per second). Specific capacities range from less than 0.01 to 61.2 gallons per minute per foot of drawdown (.002 to 12.6 liters per second per meter of drawdown).

Mean annual surface-water discharge of the basin above the gaging station Weiser River near Weiser is 788,000 acre-feet (0.97×10^9 cubic meters). The 7-day, 2-year low flow for Weiser River near Weiser is 102 cubic feet per second (2.89 cubic meters per second), and the highest peak flow was 19,900 cubic feet per second (564 cubic meters per second) in December 1955. Flow past the station Weiser River near Weiser equals or exceeds 3,000 cubic feet per second (85 cubic meters per second) 10 percent of the time. Peak flows in the tributaries at lower altitudes normally occur during January and in the tributaries at higher altitudes during April and May.

Ground water in the basin is generally of good chemical quality, with dissolved-solids concentrations generally less than 200 milligrams per liter. However, the possible contamination of some rural wells by barnyard or septic-tank pollutants is suspected.

Surface waters of the basin are also generally of good chemical quality, with dissolved-solids concentrations less than 150 milligrams per liter, except during periods of low flow in late summer when water temperatures near 25°C , algal growths, and coliform bacteria were noted in several reaches of the Weiser River.

Suspended-sediment yields from streams in the study area range from 5 tons per square mile (2 tonnes per square kilometer) to over 500 tons per square mile (200 tonnes per square kilometer).

INTRODUCTION

The study area comprises about 1,600 mi² (4,100 km²) and includes the entire Weiser River basin and small areas, both west and south of Weiser (fig. 1), which drain directly to the Snake River. The basin is sparsely populated. Populations of the four principal towns in 1970 were: Weiser, 4,071; Council, 884; Cambridge, 567; and Midvale, 172.

The economy of the basin is chiefly agricultural. The principal crops are small grains, hay, some fruit, sweet corn, sugar beets, and potatoes. Most of the crops are irrigated; however, some dryland farming is practiced. In addition, beef cattle, dairy cattle, and sheep are raised in the basin. Because the economy of the basin is based so largely on irrigated agriculture, the water resources of the basin are of vital concern to the inhabitants. An understanding of the basin's water resources would allow for their more efficient use.

Figure 1

Objectives of Study

The U.S. Geological Survey undertook this study as part of a continuing cooperative program of water-resources investigations with the Idaho Department of Water Resources (IDWR). The study was designed to meet the needs of the IDWR in planning for water-resources development and in administering water rights and the needs of water users. Specific objectives of the report are to: (1) describe the general distribution and availability of the water resources; (2) describe the chemical quality of these waters; and (3) recommend a hydrologic network for the future monitoring of ground-water-level fluctuations, surface-water flow, and water-quality changes.

Scope of Study

The major emphasis of the study was on the collection of data descriptive of the general hydrologic framework of the basin. Work accomplished during the 2-year investigation included: (1) an inventory of 370 wells; (2) the collection of streamflow data on 18 tributaries of the Weiser and Snake Rivers; (3) the reestablishment of a stream-gaging station on the Weiser River at Tamarack; (4) the collection of periodic water-level data from 24 wells; (5) study of the relation of surface and ground waters; (6) hydrologic mapping; (7) the appraisal of the quality of water resources; (8) the collection of suspended-sediment data for several tributary and Weiser River sites; and (9) an evaluation of the present use of water.

Previous Studies

Several reports relating to various aspects of the water resources of the basin provided information useful to this overall assessment of the water resources. The most noteworthy reports include: (1) Walker and Sisco (1964), which evaluated the occurrence of ground water in the Midvale and Council areas; (2) Young and Mitchell (1973), and Young and Whitehead (1975), which evaluated the geothermal potential of parts of the basin; and (3) a feasibility study by the U.S. Bureau of Reclamation (1972), which dealt with the development potential of selected areas within the basin.

Three U.S. Geological Survey open-file reports are also available. Those reports--Johnson (1941), Helland (1949), and Colbert and Young (1964)--contain general information pertaining to the development of the water resources in the basin with regard to potential reservoir sites, and summaries of existing streamflow records.

Acknowledgments

Many farmers and landowners in the Weiser River basin cooperated fully in this study by allowing access to their property, supplying information about their wells, and permitting water-level measurements to be made in their wells. Municipal officials and employees supplied information about their water systems. To all of the above, the authors are grateful.

U.S. Geological Survey Numbering Systems

Well- and Spring-Numbering System

The well- and spring-numbering system used by the U.S. Geological Survey in Idaho indicates the location of wells or springs within the official rectangular subdivision of the public lands, with reference to the Boise base line and meridian. The first two segments of the number designate the township and range. The third segment gives the section number, followed by three letters and a numeral, which indicate the quarter section, the 40-acre (16.2-ha) tract, the 10-acre (4.05-ha) tract, and the serial number of the well within the tract, respectively. Quarter sections are lettered A, B, C, and D in counterclockwise order from the northeast quarter of each section (fig. 2). Within the quarter sections, 40-acre (16.2-ha) and 10-acre (4.05-ha) tracts are lettered in the same manner. Well 14N-2W-6DCD1 is in the SE $\frac{1}{4}$ SW $\frac{1}{4}$ SE $\frac{1}{4}$ sec. 6, T. 14 N., R. 2 W., and was the first well inventoried in that tract. Springs are designated by the letter "S" following the last numeral; for example, 12N-4W-34ABB1S.

Figure 2

Gaging-Station-Numbering System

Each gaging station and partial-record station has been assigned a number in downstream order in accordance with the permanent numbering system used by the U.S. Geological Survey. Numbers are assigned in a downstream direction along the main stream, and stations on tributaries between main-stream stations are numbered in the order that the tributaries enter the main stream. A similar order is followed on other ranks of tributaries. The complete 8-digit number, such as 13266000, which is used for the station "Weiser River near Weiser," includes the part number "13," indicating that the Weiser River is in the Snake River basin, plus a 6-digit station number.

HYDROLOGIC FRAMEWORK

Climate

The climate of the Weiser River basin ranges from semiarid in the lowlands to subhumid in the higher mountains. The variation in the climatic conditions of the basin is caused primarily by the topographic relief. In general, the weather of the basin is characterized by warm, dry summers and cool, wet winters.

Mean annual temperatures recorded by the National Weather Service are 10.7°C at Weiser (altitude 2,160 ft, or 646 m) and 9.0°C at Council (altitude 2,935 ft, or 895 m). Mean monthly temperatures (fig. 3) range from about -5°C in January at Cambridge (altitude 2,650 ft, or 808 m) to about 24°C in July at Weiser. The freeze-free growing season is about 150 days at Weiser and 120 days at Cambridge (Stevlingson and Everson, 1968).

Mean annual precipitation in the basin ranges from about 10 in (250 mm) near Weiser to more than 45 in (1,100 mm) on Council Mountain (see fig. 12). Highest mean monthly precipitation occurs in December and January, while the lowest occurs in July and August. The amount of precipitation during the freeze-free growing season in the Weiser River basin ranges from 2.40 in (61 mm) at Weiser (21 percent of the mean annual) to 5.45 in (138 mm) at Council (20 percent of the mean annual).

Figure 3

Landforms and Drainage

The generally mountainous topography of the basin is bisected by a line of lowlands along the Weiser River. The lowlands are structural basins in the basalts that have been partly filled with sedimentary deposits (fig. 4). Between lowland segments, the Weiser River flows through canyons cut in the basalt. The altitudes of the valley floors range from 2,120 ft (646 m) at Weiser to 2,935 ft (895 m) at Council. Mountains on the east side of the basin rise to 8,126 ft (2,477 m) above mean sea level, and the mountains on the west side rise to 7,876 ft (2,401 m).

The Weiser River flows generally southward to the Snake River and drains an area of approximately 1,600 mi² (4,100 km²). The river is more than 110 mi (180 km) long and falls approximately 27 ft/mi (5.1 m/km) between Tamarack, altitude 4,690 ft (1,430 m), and the confluence with the Snake River at Weiser, altitude 2,100 ft (640 m).

Major east-side tributaries to the Weiser River include Crane Creek, Little Weiser River, Middle Fork Weiser River, and the East Fork Weiser River. The west side of the basin is drained primarily by Mann Creek, Keithly Creek, Pine Creek, Rush Creek, Hornet Creek, and the West Fork Weiser River.

Because the timing of the natural runoff peak in the basin does not coincide with that of the peak crop demands,

Figure 4

and because ground-water supplies are limited, several dams have been built to provide storage facilities for irrigation water. Table 1 lists the characteristics of the four major reservoirs in the basin. Although these reservoirs were designed primarily for irrigation purposes, they also are used for flood control and for recreation.

Table 1

Geology

The geologic formations in the Weiser River basin have been divided into (1) pre-Tertiary rocks, undifferentiated; (2) Miocene and Pliocene igneous rocks and associated sedimentary materials of the Columbia River Basalt Group; and (3) Tertiary and Quaternary sedimentary rocks. All lava flows in the basin are part of the Columbia River Basalt Group, and all overlying sedimentary rocks are of Tertiary and Quaternary age (Newcomb, 1970). Sedimentary rocks interbedded with lava flows are included with the Columbia River Basalt Group. The areal distribution of these units is shown in figure 4.

Surface exposures of the pre-Tertiary rocks are restricted to a few places on the higher mountains that form the western and eastern drainage divides. These rocks consist of the Seven Devils Group of Permian and Triassic age, which include some sedimentary rocks, and granitic rocks of the Idaho batholith of Cretaceous age.

The Columbia River Basalt Group is the predominant rock type in the Weiser River basin. The group crops out in hill and mountain areas and is exposed in the canyons along the Weiser River. It also underlies the valleys and the broad, undulating plain in the Crane Creek area. The individual lava flows range in thickness from a few feet to about 50 ft (15 m) (Walker and Sisco, 1964).

The sedimentary rocks of Tertiary and Quaternary age are primarily of lacustrine origin and consist mainly of clay and silt. Some sand bodies are included in the sequence, but gravel is uncommon, except in the lowlands near Weiser. A few thin layers of sand and gravel are exposed in terraces along the Weiser River near Midvale and Cambridge. These deposits are generally less than 10 ft (3 m) thick and occur at very shallow depths. Their areal extent is unknown, but they are thought to be limited to the river flood plain.

Water Use

The principal uses of water in the Weiser River basin, in order of quantities used, are irrigation, domestic, stock, and industrial.

The principal source of irrigation water for the approximately 55,000 acres (22,000 ha) of irrigated land is the Weiser River and its tributaries. Some supplemental irrigation water is supplied from wells, primarily in the southern part of the basin near Weiser.

Domestic and stock water supplies for the basin are derived chiefly from individual wells and springs. Municipal water supplies are obtained from both ground- and surface-water sources. The towns of Council, Cambridge, and Midvale receive water from seven wells open to basalt of the Columbia River Basalt Group. The city of Weiser obtains water from three wells open to the sedimentary-rock aquifers and also from the Snake and Weiser Rivers.

Industrial water use in the basin is limited to the lumbering industry in the central and northern parts of the basin. The primary use of the water by this industry is for mill ponds, which results in very little consumptive use. Most industrial water supplies are obtained from surface-water sources with some supplemental ground-water pumpage.

Water rights and applications for appropriation of water granted by the Idaho Department of Water Resources for surface water in the Weiser River basin as of April 1974 totaled slightly more than 1,000 ft³/s (28 m³/s). Table 2 shows the amount of allocated water (decrees, licenses, and permits) for the Weiser River and its major tributaries. These appropriations are primarily for surface water. Estimates of ground-water pumpage for irrigation and other uses were beyond the scope of this investigation.

Table 2

GROUND WATER

Occurrence

Ground water occurs in all the geologic units of the Weiser River basin. The areal distribution and water-bearing characteristics of these units are shown in figure 4.

The most important and productive aquifers in the basin are in the Columbia River Basalt Group. The group is exposed in the mountains and also underlies the valleys and lowlands throughout the basin. Ground water in the basalt occurs mainly in fractures, joints, and breccia zones of the individual lava flows and in sand and gravel beds that are interlayered with basalt flows. Ground water occurs under both water-table and artesian conditions. The water-table occurrence is limited mostly to the valleys and uplands of the northern part of the basin, whereas artesian conditions occur in the basalt underlying the valleys and lowlands of the central and southern parts of the basin.

Sedimentary rocks of Tertiary and Quaternary age and their aquifers are restricted to the valleys and lowlands. These aquifers are composed primarily of sand, silt, and clay. The main water-bearing zones are thin layers of sand and gravel. Ground water in the sedimentary-rock aquifers is generally confined or semiconfined in all parts of the basin, except for that in the lowlands adjacent to Weiser,

where water-table conditions exist. Water-table conditions also are found in the surficial sand and gravel deposits adjacent to the Weiser River near Cambridge and Midvale.

The occurrence of ground water in the pre-Tertiary rocks, which are exposed only in isolated places in the higher mountains, is limited to fractures and weathered zones. The fractures and weathered zones are the principal sources of water for springs in these areas.

Source

Most of the ground water in the Weiser River basin is derived from precipitation falling within the drainage basin. An unknown but probably small quantity of recharge to the ground-water system probably results from infiltration of imported water introduced into the basin by the Lower Payette canal.

The basaltic rocks exposed in the catchment areas of the surrounding uplands and mountains also compose the principal aquifers underlying the valleys and lowlands. The principal source of recharge to the basalt aquifers is precipitation falling on the basalt in the mountains. This basalt accepts snowmelt through its fractures, joints, and other connected pores which also serve as conduits that transmit water to the aquifers underlying the valleys and lowlands. Recharge to the basalt aquifers occurs principally during periods of snowmelt.

Sedimentary-rock aquifers are recharged by infiltration of water from snowmelt runoff, streams, canals, ditches, and irrigated fields. It is also suspected that some recharge may result from vertical upward percolation of water from the underlying artesian basalt aquifers. The sedimentary-rock aquifers are recharged primarily during snowmelt runoff and the irrigation season.

Water-Level Fluctuations

Ground-water levels in the Weiser River basin fluctuate in response to snowmelt runoff, application of irrigation water, and ground-water pumping. Generally, the magnitude of these fluctuations is greatest in the sedimentary-rock aquifers and least in the basalt aquifers.

Fluctuations of ground-water levels in selected wells in the Weiser River basin are shown on hydrographs (fig. 5), and the well locations are shown in figure 6.

Generally, water levels in wells in both the basalt and the sedimentary-rock aquifers in the Weiser River basin begin to rise in response to snowmelt runoff. The water levels continue to rise during the snowmelt-runoff period and then gradually decline.

Water levels in well 12N-5W-34ABC1 completed in the sedimentary-rock aquifer near Monroe Creek, and well 17N-1W-15AAC1 completed in the basalt aquifer near Fruitvale, show water-level fluctuations that correspond with snowmelt runoff. Water levels in both wells rise during snowmelt runoff and then gradually decline throughout the summer, fall, and winter. The natural hydrograph of well 17N-1W-15AAC1 has been slightly distorted because of pumping. Water-level fluctuations for several other wells in figure 5 also show the same seasonal trends.

Figure 5

Figure 6

In areas where excess irrigation water infiltrates to the underlying aquifer, water levels start to rise in conjunction with snowmelt runoff. However, the water levels continue to rise throughout the summer (growing season) in response to the infiltrating irrigation water and then gradually decline after the irrigation season ends.

Water levels in well 11N-6W-25CACl completed in the sedimentary-rock aquifer west of Weiser and well 12N-4W-31DBB1 completed in the sedimentary-rock aquifer near Mann Creek (fig. 5) show water levels affected by the infiltration of irrigation water. Water levels rise during the irrigation season and generally reach a maximum in September.

Water-levels in areas affected by ground-water pumping for irrigation show declines beginning in late spring or early summer. These declines continue until fall when water levels start to recover after the pumping season. The effects of ground-water pumping in different parts of the Weiser River basin are shown by the following hydrographs (fig. 5): well 10N-5W-16BBC1, completed in the sedimentary-rock aquifer east of Weiser; well 13N-1W-32ACD1, completed in the basalt(?) aquifer near Crane; wells 13N-4W-12CDCl, completed in the sedimentary-rock(?) aquifer and 13N-3W-10CDD1, completed in the basalt aquifer near Midvale; and well 16N-1W-3DDD2, completed in the sedimentary-rock aquifer near Council.

Movement

The general direction of ground-water movement in parts of the Weiser River basin can be inferred from contours on the potentiometric surface based on 370 water levels measured or reported in the fall of 1975 (fig. 6). Data for all inventoried wells in the Weiser River basin are given in basic-data table A. The ground-water movement is perpendicular to the potentiometric-surface contours and down-gradient. The potentiometric surface (fig. 6) includes the surface of the saturated zone in the areas where the ground water is unconfined and the hydrostatic head in areas where the ground water is semiconfined or confined.

Ground water in the Weiser River basin in general moves from areas of higher altitude to areas of lower altitude. Potentiometric contours are shown only along the axis of the Weiser River and its major tributaries because well data are not available for other parts of the basin. Although there are no well data available in the mountainous areas, it is assumed that the ground water moves from these catchment areas to the lowlands and valleys through basalt of the Columbia River Basalt Group.

The potential for ground-water movement is shown on figure 6 in the greatest detail in the valley segments at Council, Cambridge, and Midvale, and in Indian Valley and Crane Creek valley. The potential gradient is rather flat

Basic - data Table A

in these valleys and ground water moves toward the Weiser River and other streams where it is discharged by evapotranspiration and inflow to the streams.

The direction of ground-water movement near Weiser and along Mann Creek Valley is controlled primarily by recharge resulting from infiltration losses of applied irrigation water. Ground water moves toward the Weiser and Snake Rivers from the irrigated areas adjacent to each river. In the Mann Creek valley, ground water moves from the irrigated areas along the eastern side of the valley southwestward to Mann Creek, which flows along the western edge of the valley.

In addition to the lateral ground-water movement implied in figure 6, ground water in the semiconfined and confined systems may also move vertically. Vertical movement is controlled by the hydrostatic head differences and the hydraulic conductivity of the materials in which the water is moving. In the Cambridge and Midvale areas, ground water moving upward from the basalt aquifers may be an important source of recharge to the sedimentary-rock aquifers.

Discharge

Ground water is discharged in the Weiser River basin by springs, seepage to stream channels, evapotranspiration, pumping, and subsurface outflow.

Springs and seeps in the Weiser River can be divided into two groups; intermittent and perennial. Generally, the intermittent springs are in the lowlands and valleys. These springs usually head in small draws and drain local shallow, unconfined aquifers that respond directly to the infiltration of local precipitation. The perennial springs, for the most part, are found in the high mountains of the basin. The base flow of the Weiser River and most of the perennial streams is derived from these upland springs and seeps.

Evapotranspiration, which includes evaporation from land and water surfaces and transpiration from vegetation, occurs mainly in the lowlands and valleys where the potentiometric surface is near or above the land surface.

Ground-water pumping is a means of discharge in many parts of the Weiser River basin. Hydrographs for selected wells (fig. 5) located in the lowlands near Council, Indian Valley, Midvale, and Weiser show the effect of ground-water pumping.

Subsurface outflow from the Weiser River basin occurs near Weiser. The outflow is through the sand and gravel of the sedimentary-rock aquifer and is toward the Snake River

(fig. 6). An estimate of the amount of subsurface outflow to the Snake River was made using available data and the following equations:

$$T = 0.1337 \times SC \times 2,000 \quad (1)$$

(Thomasson and others, 1960), and

$$Q = TIL \quad (2)$$

(Ferris and others, 1962), where

T = transmissivity, in feet squared per day,

SC = specific capacity, in gallons per minute per foot of drawdown,

Q = discharge, in cubic feet per day,

I = hydraulic gradient, in feet per mile, and

L = width, in miles, of the cross section through which the discharge occurs.

Assuming an average specific capacity (SC) of 10 (gal/min)/ ft of drawdown (2.06 [L/s]/m of drawdown) as estimated from drillers' logs, a transmissivity (T) of 2,670 ft²/day (248 m²/day) is calculated using equation 1. Using a transmissivity (T) of 2,670 ft²/day (248 m²/day), a hydraulic gradient (I) of 13 ft/mi (6.4 m/km) as determined from wells near Weiser, and a cross-section width (L) of 17 mi (27 km), the subsurface outflow from the Weiser River basin is 590,000 ft³/day (16,700 m³/day), or less than 7 ft³/sec (0.20 m³/s) using equation 2.

Thermal Water

Thermal ground water is present in several areas of the Weiser River basin. Preliminary chemical and physical data descriptive of thermal water from five springs and four wells in the Weiser River basin were collected by Young and Mitchell (1973). The temperatures of these waters ranged from about 25° to about 90°C, and the discharges ranged from less than 1 gal/min (0.063 L/s) to 431 gal/min (27.2 L/s). The thermal springs issue from basalt or from alluvium in proximity to basaltic outcrops, and all wells are thought to penetrate and receive water from basalt.

The southern part of the Weiser River basin probably has the greatest potential for geothermal exploration and development. Young and Whitehead (1975) studied the Weiser Hot Springs and the Crane Creek Hot Springs areas, located in the southern part of the basin approximately 5 mi (8 km) northwest and 12 mi (19 km) east of Weiser, respectively.

Well Yields

Sufficient ground water for domestic and stock supplies can be obtained almost everywhere in the Weiser River basin. Adequate yields for irrigation and municipal supplies, with the exception of the sedimentary-rock aquifer near Weiser, are probably limited to the basalt aquifers. The sedimentary-rock aquifer near Weiser does yield adequate amounts of water for irrigation.

Yields and specific capacities of wells in the basalt are highly variable. Reported well yields from drillers' logs of wells penetrating the basalt aquifers range from 3 to 1,835 gal/min (0.2 to 122 L/s). Specific capacities determined from drillers' logs range from 0.06 to 52.4 (gal/min)/ft of drawdown (0.01 to 11.0 [L/s]/m of drawdown). However, a yield of 1 gal/min for each foot of penetration (0.21 L/s for each meter of penetration) (Newcomb, 1959) in the saturated basalt may be a reasonable approximation of the expected yields from these aquifers. Reported yields (basic-data table A) averaged slightly less than 2 gal/min for each foot of penetration (0.4 L/s for each meter of penetration). Several wells completed in basalt in Council, Indian Valley, Cambridge, Midvale, and the area near Crane Creek Reservoir yield adequate amounts of water for irrigation and municipal needs.

Reported yields from the sedimentary-rock aquifers range from 1 to 1,647 gal/min (0.063 to 104 L/s) (basic-data table A). Specific capacities of wells in these aquifers are highly variable and range from less than 0.01 (gal/min)/ft of drawdown (.002 [L/s]/m of drawdown) for wells penetrating finer grained materials to 61.2 (gal/min)/ft of drawdown (12.6 [L/s]/m of drawdown) for wells penetrating a sand and gravel aquifer near Weiser. The yields of wells in the sedimentary-rock aquifers are directly related to the thickness of saturated sand and gravel encountered in the wells; for example, the thicker the sand and gravel beds in the saturated material, the larger the well yields.

Well Construction and Development

Proper well construction and development are essential to insure optimum well yields, prevent caving, and obtain maximum economic well life. In the basalt aquifers, the material surrounding the well, in most instances, is stable, and the water enters the well directly from fractures and joints. However, in the sedimentary-rock aquifers and interbedded sedimentary rocks or rubble zones of the basalt aquifers where water is derived from unconsolidated materials, a casing is necessary to support the well. The casing should be perforated or a well screen should be installed to admit water to the well. If perforations or screens are installed at all permeable water-bearing zones penetrated, yield will be maximized. Perforated casing or well screens should generally not be installed adjacent to silt, clay, or fine sand because only small quantities of muddy water would be produced.

The optimum size of the perforations or screen openings depends on the grain size of the aquifer materials. The perforations or screen openings should be sized to allow at least 50 percent of the fine-grained aquifer materials to pass through the openings. This will then remove the finer grained materials, leaving the coarse aquifer materials around the well to form a more permeable zone.

Another method of well construction involves the use of an artificial gravel envelope around the perforated or screened intervals of the well. The gravel pack increases the effective diameter of the well and prevents the fine-grained material from moving into the well. The size of the gravel used in packing a well is dependent upon the size of the aquifer materials. Generally, the size of gravel used is four times larger than the coarser 25 percent of the aquifer materials. The size of perforations or screen openings should be about three-fourths of the size of the gravel used to pack the well.

After installation of perforations, screens, or gravel pack, the well should be developed to remove the fine-grained aquifer materials from around the perforated or screened intervals. Two common methods of well development are pumping and surging.

Development by pumping is accomplished by initially pumping the well at a low discharge rate until the water becomes clear. The well is then pumped at a higher discharge until the water once again clears. This procedure is continued until the maximum discharge rate is reached. Pumping is then stopped and the water level in the well is allowed to recover. The above outlined pumping cycle is then repeated until concentrations of fine-grained materials in the water are reduced to an acceptable level.

Surging the well requires the use of a surge block or plunger. The block is operated above the perforated or screened interval and forces water in and out of the well through the perforations. This action pulls the finer grained aquifer material into the well where they can be removed by a bailer. This process should be continued until all fine-grained material is removed.

Careful well development increases the likelihood of obtaining maximum well yield with minimum drawdown. A properly developed well will usually have a longer life.

Ground-Water Contribution to Surface-Water Flow

Base flow of streams is that part of streamflow which is derived from ground-water discharge. Ground-water discharges to streams in the Weiser River basin by means of springs, seeps, and seepage directly into the main stream channels--drainage directly from the rock formations or soil horizons. The effect of ground-water discharge to a stream is usually identifiable by the specific conductance of the stream water. As the specific conductance of the stream nears that of the ground-water body, the ground-water contribution to the stream approaches 100 percent of the streamflow.

Specific-conductance values and the corresponding discharges for the Middle Fork Weiser River and Scott Creek are shown in figure 7. Ground-water contribution to the Middle Fork Weiser River approaches 100 percent of the streamflow during the period of relatively constant specific-conductance values (mid-summer to early spring). The periods of lower specific conductance and higher discharges indicate periods of snowmelt runoff.

Scott Creek, although not a perennial stream, is also influenced by ground-water discharge. However, the ground-water system is not sufficient to maintain streamflow throughout the summer months.

Figure 7

SURFACE WATER

The largest source of readily available water in the Weiser River basin is surface water. The collection of streamflow data to describe this resource began in 1890 with the establishment of the gaging station Weiser River near Weiser. Since then, 38 gages have been operated from time to time to record daily flows, and two crest-stage gages have been used to record peak flows. At present, the stream-gaging network in the basin consists of three continuous-recording gages and one crest-stage gage. These gages are West Branch Weiser River near Tamarack, Weiser River near Cambridge, Weiser River near Weiser, and Dixie Creek near Cambridge (basic-data table B and fig. 8).

During this study, April 1974 through December 1975, the gage Weiser River at Tamarack was reactivated to provide continuous flow record. In addition, monthly discharge measurements were made at 18 sites to aid in defining the distribution of flow throughout the basin. Streamflows were measured at 20 other sites during periods of high flow when sediment transport was also high. Some of these measurement sites were at discontinued gaging station locations. Gaging stations, measurement sites, basin characteristics, and periods of streamflow records are listed in basic-data table B. Locations of the stations and sites are shown in figure 8. Discharge measurements made during this study and

Basic data table 3

Figure 8

concurrently collected water-quality data are listed in basic-data tables G and H. Discharge measurements made at other miscellaneous sites in the basin through 1967 were summarized by Decker and others (1970). Subsequent miscellaneous measurements in the basin have been published yearly in "Water Resources Data for Idaho, Part 1, Surface-Water Records."

Annual Discharges

The gaging station Weiser River near Weiser measures most of the water flowing from the basin and has the longest record in the basin. Thirty-two complete water years of record have been collected intermittently at this gage, beginning with the 1896 water year and continuing through the 1975 water year. The mean annual discharge (long-term average discharge) for these 32 years is 1,170 ft³/s (33.2 m³/s), or about 850,000 acre-ft/yr (1.05x10⁹m³/yr).

The record for Weiser River near Weiser was extended using data from other stations to improve the evaluation of long-term trends in the streamflow of the basin. The stream-gaging stations Crane Creek at mouth near Weiser and Weiser River above Crane Creek near Weiser operated concurrently for 31 years when the station Weiser River near Weiser was not in operation. As the total drainage area of these two stations is 99.2 percent of that at Weiser River near Weiser gage, and as no significant inflow occurs between the two upper stations and the station Weiser River near Weiser, the combined flow of the two upper stations is virtually the same as at Weiser River near Weiser. The mean annual discharge for 63 years of the period 1896-1975 (32 years, Weiser River near Weiser; and 31 years, Weiser River above Crane Creek near Weiser, plus Crane Creek at mouth near Weiser) is 1,070 ft³/s (30.4 m³/s), or 778,000 acre-ft/yr.

($0.96 \times 10^9 \text{ m}^3/\text{yr}$). Three gaging-station records for areas near the basin were used to extend the record at Weiser River near Weiser by linear regression to cover the missing periods, water years 1905 through 1911 and 1915 through 1921. The mean annual discharge for the 77-year period is $1,090 \text{ ft}^3/\text{s}$ ($30.8 \text{ m}^3/\text{s}$), or $788,000 \text{ acre-ft/yr}$ ($0.97 \times 10^9 \text{ m}^3/\text{yr}$). The entire extended record is shown in figure 9 along with the mean annual discharges for the various periods of record.

Streamflow as measured at the gaging station Weiser River near Weiser is representative of the surface-water conditions elsewhere in the basin. Other gaging stations on the Weiser River showed variations in annual discharge that are similar. Some of the tributary subbasins exhibit different annual runoff patterns because streamflows are regulated by reservoir impoundments and releases that do not correspond with natural runoff characteristics.

Figure 9

Monthly Discharges

Monthly flow records provide a convenient way of looking at the hydrologic characteristics of a stream, such as the seasonal flow distribution.

Hydrographs of mean monthly discharges (average of all discharges for the same month) for the six Weiser River gaging stations (fig. 10) show how flow is distributed in the Weiser River with respect to time. The monthly mean discharges (average of the daily discharges--average daily rate of flow--that occurred during that particular month) at Weiser River at Tamarack, near Cambridge, and near Weiser, operating during the project are also shown so the data collected during the project period can be compared with long-term means. The figure shows that monthly flows in the Weiser River were generally higher than average during this study, except for the period October 1974 through April 1975. The lower-than-normal flows during the period appear to be the result of lower-than-normal precipitation during the October 1974 through January 1975 segment and lower-than-normal temperatures during the February 1975 through April 1975 segment. National Weather Service Climatological Data Summaries for the period show that the February 1975 through April 1975 segment received above-average precipitation. This, combined with the low temperatures, resulted in the delayed and higher-than-normal runoff peaks in the

Figure 10

1975 water year (the 12-month period October 1, 1974, through September 30, 1975).

Mean monthly discharge for selected tributaries based on discontinued gaging-station records are shown in figure 11. Four of the tributaries, Middle Fork Weiser River, Pine Creek, Little Weiser River, and Mann Creek, are natural-flow streams and have hydrographs characteristic of such streams. In contrast, the hydrographs for Lost Creek and Crane Creek show influences of reservoir releases. The high flows of Lost Creek in April and May probably indicate a low storage capacity in relation to inflow for Lost Valley Reservoir during these months. If this is true, the high flows are the result of spillage over dam gates. The high summer flows are sustained by releases of water from storage in the reservoir. The Crane Creek stations 13264500 and 13265500 show the high summer flows from reservoir releases. The high-flow segments of the Crane Creek hydrographs in January, February, March, and April are the result of high-flow years when inflow exceeds the capacity of the reservoir and releases are required to prevent flows over the spillway.

The hydrograph for West Fork Weiser River shows some characteristics of both regulated and natural streams. The higher flows during the summer months are the result of

Figure 11

releases from Lost Valley Reservoir. During the remainder of the year, the stream appears to be only slightly affected by the operation of the reservoir. However, because the drainage area above the reservoir accounts for more than one-third of the area of the subbasin, the effects of storage may be important.

To establish a basis for estimating mean monthly discharge at other sites, the series of discharge measurements made on 18 streams in the Weiser River basin were used to estimate the monthly mean flow by the method proposed by Riggs (1969). This method is a statistical correlation technique utilizing the measured discharges of the ungaged streams concurrently with discharges at a nearby continuous-recording stream-gage site. Two recording stations were used for correlation of streams in the Weiser River basin. The monthly mean discharges for the higher altitude streams were estimated using the reactivated gaging station Weiser River at Tamarack. Estimates for the lower altitude streams were made using the gage on Big Willow Creek near Emmett (not shown in fig. 8--located about 5 mi (8 km) south of study area). Although Big Willow Creek is not within the Weiser River drainage, it drains country similar and adjacent to much of the lower Weiser River basin. The resultant estimates of monthly mean discharges for the 1975 water year for the 18 selected streams are given in basic-data table C.

Basic-data table C.

The process used to convert the monthly mean discharges to the mean monthly discharge for each stream in basic-data table C is as follows: (1) the monthly mean discharges developed by the Riggs method were used to determine an annual mean discharge for the 1975 water year; (2) the annual mean discharge was then adjusted to a mean annual discharge by assuming the same relation of 1975 annual mean to mean annual exists at the measurement site and the correlation station; (3) the mean monthly discharge for each month was estimated by a percentage of the mean annual flow for each month as determined by nearby station records. The mean monthly discharges for each stream are also given in basic-data table C. In addition, the mean monthly and mean annual runoff (runoff shows the depth in inches to which the drainage area would be covered if all the streamflow for a given period was uniformly distributed) for each stream have been computed and are also given in the same basic-data table. Bar graphs depicting the mean monthly runoffs of the selected tributaries and at three Weiser River stations are shown in figure 12.

Subbasins within the Weiser River basin exhibit one of two different runoff patterns. The particular pattern depends somewhat on the altitude of the subbasin. The streams in the lower altitudes of the basin normally reach their peak monthly runoff in January and normally can be

Figure 12

expected to go dry at least 1 month of the year (some are dry about 9 months of the year), while the streams in the higher altitudes of the basin have peak monthly runoff in April and May and flow year round.

Runoff from the two different areas is also shown by the bar graphs for the Weiser River stations. For Weiser River at Tamarack in the northern part of the basin, high monthly runoff occurs in April and May. High monthly runoff near the middle of the basin, as shown by the station Weiser River near Cambridge, occurs from March through June. High monthly runoff in the southern part of the basin, as shown by the station Weiser River near Weiser, occurs from January through June.

The mean annual runoff estimates computed for the monthly measurement sites and listed in basic-data table C are also shown in figure 12. The runoff data used in this map were supplemented by data from gaging-station records wherever possible.

Daily Discharges

The gaged daily-discharge record provides the most detailed information commonly available about the flow characteristics of a stream. However, streamflow records of more than a few years' duration contain large masses of data that must be summarized to permit efficient use of the data. A number of data summarizing techniques are available. The two techniques used in this report are conversions of the data into the duration hydrographs and the flow-duration curves. The duration hydrograph is produced by examining the daily discharges for the period of record being considered, determining the highest and lowest flows that have occurred, and the flows that have been exceeded 50 percent of the time. Computer program constraints limit record periods to 9, 19, 29, 39, and 49 years. Thus, not all of the available data were used to generate the duration hydrographs of this report. Figures 13 and 14 illustrate the lowest, highest, and median (50 percent exceeded) flows obtained from this analysis.

The highest median discharges for the six Weiser River stations (shown in fig. 13) occurred in April and May as a result of normal spring snowmelt runoff. However, the highest daily discharges occurred during the period December through February. These discharges are usually the result of rain on a snowpack.

Figure 13

Figure 14

Average lowest discharges for all measurement sites, as indicated by the median line, occur in late summer. The isolated 1-day low discharges on the Weiser River at Tamarack hydrograph (fig. 13) are probably the result of the draining and filling of the log pond at Tamarack. When the pond is flushed, the discharge at the gage is increased. When the pond is filled, the flow is reduced and produces the isolated lows.

Duration hydrographs for selected tributaries are shown in figure 14. The hydrographs for West Branch Weiser River, Middle Fork Weiser River, Little Weiser River, Pine Creek, and Mann Creek are representative of those streams that are not regulated by reservoir storages and releases. All streams but Mann Creek normally peak in April-May, as shown by the median line. The runoff peak (April) of Mann Creek probably occurs early because the stream drains a lower altitude than most of the tributaries shown. Also, the sub-basin faces mostly south; therefore, most slopes get sun early in the year, and snow melts earlier.

The duration hydrographs for Lost Creek, West Fork Weiser River, and Crane Creek gaging stations show the effects of regulation. The closer the station to the point of regulation, the more pronounced the effects of regulation. Noticeable effects include long periods of time with the same discharge and periods of no flow. The farther

downstream, the less the effects of regulation on the stream. The effects of regulation at the gage on Lost Creek are more apparent than at the downstream station on the West Fork Weiser River. Even though the hydrographs for both stations on Crane Creek exhibit the effects of regulation, the downstream station curves show the lesser effects. A comparison of the curves for both of these stations shows that some flow is generated between the stations.

The flow-duration curve, the second technique, shows the percentage of time that specified discharges have been equaled or exceeded during the period of record examined. The computer program that produces the duration-curve data examines all daily flow data during the period being considered--the entire period of record for this report--and produces the frequency curve without regard to the particular day or year in which a flow occurred. Thus, the duration curve can be used to determine the flow (daily discharge) that is exceeded a specified percent of the time.

For example, the duration curves for the Weiser River gaging stations (fig. 15) show that 10 percent of the time (36.5 days a year), the discharge equals or exceeds the following: Weiser River at Tamarack, 136 ft³/s (3.9 m³/s); Weiser River at Starkey, 358 ft³/s (10 m³/s); Weiser River near Council, 1,180 ft³/s (33 m³/s); Weiser River near Cambridge, 1,790 ft³/s (51 m³/s); Weiser River above Crane

Figure 15

Creek, 2,650 ft³/s (75 m³/s); and Weiser River near Weiser, 3,000 ft³/s (85 m³/s). This curve generally shows a logical increase in discharge from upstream stations to downstream stations on the Weiser River. The exceptions to this orderly increase are at the lower river stations during low-flow periods. The drop in the curves for Weiser River above Crane Creek and Weiser River near Weiser is probably the result of increased diversions for irrigation from the river combined with a decrease in natural inflow in late summer and early fall.

Flow-duration curves for selected tributaries are shown in figures 16, 17, and 18. With the exceptions of Lost Creek, West Fork Weiser River, and the two Crane Creek stations, the curves represent unregulated tributaries in the basin. Flow-duration curves for all regulated streams, except Crane Creek at mouth, show they can experience some period of no flow, as indicated by the curve leaving the plot (for example, see figure 16; Lost Creek leaves graph at 98 percent). The curve for Crane Creek at mouth (fig. 18) nears the bottom of the graph (0.1 ft³/s, or 0.0021 m³/s), but the flow at this station is sustained by spring flow and has never experienced a zero flow in 52 years of record. Other tributaries also have periods of no flow, as shown by figure 18 for Monroe Creek and Mann Creek and figure 17 for Rush Creek. Upstream irrigation diversions on Monroe and

Figure 14

Figure 17

Figure 18

Rush Creeks partially affect the discharges of these stations and may account for the no-flow periods. The periods of no flow for Mann Creek may also have been caused by a diversion.

In an area where agriculture depends on streamflow for irrigation water, a more useful flow-duration curve is one which shows the percentage of time that flows are equaled or exceeded during the irrigation season. The irrigation season (May 1 through September 30) flow-duration curves for the Weiser River stations are shown in figure 19. This figure shows that flow in the Weiser River for 10 percent of the time during the irrigation season equals or exceeds 104 ft³/s (2.9 m³/s) at Tamarack, 320 ft³/s (9.1 m³/s) at Starkey, 1,010 ft³/s (29 m³/s) near Council, 2,950 ft³/s (84 m³/s) near Cambridge, 2,500 ft³/s (71 m³/s) above Crane Creek, and 1,830 ft³/s (52 m³/s) near Weiser.

Figure 19

Low-Flow Discharge

Low-flow characteristics of a stream are important in determining the adequacy of streamflow to supply water for irrigation, industrial, and municipal needs, to maintain fish populations, and to remove wastes during critical low-flow periods. The low-flow data presented in this section were derived from gaging-station records where the period of record was 10 years or more, or by correlation with nearby stations using techniques given by Riggs (1973).

Low flows refer to the lowest average flow for periods of 1 day of the year, 3 consecutive days of the year, 7 consecutive days of the year, and 14 consecutive days of the year. The flows used are the average for the indicated period and generally are reported in cubic feet per second. Thus, a 7-day low flow of $20 \text{ ft}^3/\text{s}$ ($0.6 \text{ m}^3/\text{s}$) means that during the 7-day period, daily discharge averaged $20 \text{ ft}^3/\text{s}$ ($0.6 \text{ m}^3/\text{s}$). In addition to a flow period, recurrence intervals are also reported in discussing low-flow characteristics. For example, the 7-day, 10-year low flow for the Weiser River at Tamarack is $3.1 \text{ ft}^3/\text{s}$ ($0.09 \text{ m}^3/\text{s}$). The 10-year period cited in the example is the recurrence interval, or the average time period between low flows lower than the specified magnitude. The recurrence interval of 10 years does not indicate that lower than specified flows will occur at 10-year intervals; it indicates only that the average

interval between such occurrences is 10 years. Because probability is the reciprocal of the recurrence interval, the example can be restated to say that there is a 10 percent chance--or the probability is 0.10--that the 7-day low flow at the Weiser River at Tamarack will be lower than $3.1 \text{ ft}^3/\text{s}$ ($0.09 \text{ m}^3/\text{s}$) in any one year. Low-flow characteristics of the Weiser River and selected tributaries for 1-day, 3-day, 7-day, and 14-day periods and recurrence intervals of 2, 5, 10, and 20 years are given in basic-data table D.

Basic data table D

High-Flow Discharge

High-flow characteristics of streams are important in the proper design of dams, levees, bridges, culverts, and other structures which are subject to damage from excessively high streamflows. They are presented as frequencies in a manner similar to that used for the low-flow characteristics.

High-flow frequencies are listed in basic-data table E for the Weiser River and selected tributaries for the 1-day, 3-day, 7-day, 15-day, and 30-day high-flow periods for recurrence intervals of 2, 5, 10, and 25 years. For example, the 7-day high-flow discharge with a recurrence interval of 10 years for the Weiser River at Tamarack is 542 ft³/s (15 m³/s).

For most streams in the Weiser River basin, much of the total annual discharge of each stream occurs during a short high-flow discharge period. This is especially true of the low-altitude, low-precipitation streams of the southern part of the basin.

Basic data table E

Floods

The largest floods in the Weiser River basin usually occur during the winter months and are generally caused by rapid snowmelt resulting from rain falling on the snowpack, unseasonably warm temperatures, or both. Winter floods of a more localized nature are usually the result of a sudden thaw which breaks up river ice. The river ice begins to flow and creates ice jams, causing the streams to overflow.

A parameter frequently used in describing floods is the annual peak discharge. The discharge referred to is the highest momentary flow experienced during a water year at a particular site. Most commonly, annual peak-discharge data are collected at gaging stations. However, such annual peak discharges can also be measured at other sites by indirect methods involving surveys of water profiles and stream cross sections and mathematical computation of flow through the surveyed reach. This has been done at discontinued gages and ungaged sites in the Weiser basin. For example, indirect measurements of the December 1955 flood were made at the discontinued gaging station Rush Creek at Cambridge and at the ungaged site South Fork Crane Creek near Crane, and have been reported by Decker and others (1970).

Analyses of annual peak-discharge data are used by hydrologists and engineers to estimate flood-hazard areas, determine optimum sizes for bridges and culverts, and to

plan for other hydraulic structures. Such analyses involve determination of the frequency of occurrence of peaks. A procedure to be used by Federal agencies in the analysis of peak-discharge data has been proposed by the Water Resources Council (1967). The log-Pearson Type III frequency analysis procedure has been followed in this report, and the frequency curves shown in figures 20, 21, 22, and 23 have been derived using the proposed procedure.

The magnitude and frequency of annual peaks on the Weiser River for the six gaged sites are shown in figure 20. The series of dashed lines show that the peak discharges expected to be equaled or exceeded on the average of once in 10 years are 800 ft³/s (23 m³/s) for the Weiser River at Tamarack; 2,280 ft³/s (65 m³/s) for the Weiser River at Starkey; 5,170 ft³/s (146 m³/s) for the Weiser River near Council; 8,160 ft³/s (231 m³/s) for the Weiser River near Cambridge; 12,600 ft³/s (357 m³/s) for the Weiser River above Crane Creek near Weiser; and 17,100 ft³/s (484 m³/s) for the Weiser River near Weiser. Magnitudes and frequencies of peak discharges for tributary basins are presented in figures 21, 22, and 23. These figures can be used in the same manner as figure 20.

The highest flood of record (38 years) on the Weiser River near Weiser is 19,900 ft³/s (564 m³/s), which was recorded during December 1955. The same flood was also the

Figure 20

Figure 21

Figure 22

Figure 23

highest of record (36 years) at the station Weiser River near Cambridge with $10,100 \text{ ft}^3/\text{s}$ ($286 \text{ m}^3/\text{s}$). The recurrence intervals for the December 1955 flood at these stations, based on the frequency curves, are 23 years for Weiser River near Weiser, 40 years for Weiser River near Cambridge, 30 years for Weiser River near Council, and in excess of 100 years for Weiser River at Tamarack. In contrast, the peak discharge for the 1975 water year of the Weiser River near Weiser was $6,700 \text{ ft}^3/\text{s}$ ($190 \text{ m}^3/\text{s}$), with a recurrence interval of 1.2 years; Weiser River near Cambridge, $5,060 \text{ ft}^3/\text{s}$ ($143 \text{ m}^3/\text{s}$), 2 years; and Weiser River at Tamarack, $707 \text{ ft}^3/\text{s}$ ($20 \text{ m}^3/\text{s}$), 6.2 years.

WATER QUALITY

Three water-quality stations were established on the Weiser River. These stations were sampled monthly from April 1974 through December 1975 for chemical constituents and during periods of high flows for suspended-sediment concentrations. Nineteen water-quality stations were established on tributary streams and were sampled for chemical constituents during periods of low flows and for suspended-sediment concentrations during periods of high flows. An additional 13 stations, along with several other miscellaneous sites, were sampled for suspended-sediment concentrations during periods of high flows.

From August 20 to August 28, 1974, a survey of stream-flow losses and gains was made along the Weiser River from river mi 94.8 (km 153) above the mill pond at Tamarack to mi 0.0 (km 0.0) at the mouth in Weiser. During the same period, the river was sampled at 32 sites for nutrients, dissolved oxygen, dissolved solids, pH, and temperature. In addition, sampling was done at selected sites for coliform bacteria concentrations and pesticide levels.

To determine the chemical character of the ground water within the basin, municipal wells in the communities of Weiser, Midvale, Cambridge, and Council were sampled during August 1974. In August 1975, 27 stock, irrigation, and domestic wells were sampled throughout the Weiser River basin.

The chemical and biological characteristics of water determine its suitability for domestic, agricultural, and industrial use.

The physical factors of the stream, such as flow velocity, volume of water, bottom contours, rate of water exchange, depth, light penetration, and temperature, play vital roles in the chemical reactions and the nature of biological activities.

The natural aquatic environment includes diverse species of plants and animals that vary in their chemical and physical needs. Natural and manmade sources introduce a variety of organic and inorganic materials into the aquatic environment. Within the aquatic environment, these materials are transported, converted, respired, incorporated, excreted, and deposited.

Many of man's various physical activities that maximize the use of water often adversely affect its quality. Alteration of streambeds by channelizing, filling, diking, removing sand and gravel, and impounding may have adverse effects on water quality. In addition, activities on the watershed--clearing, logging, grazing, and leveling--can affect the quality of water entering streams.

Table 3 relates chemical and biological characteristics to significance, concentration of normal occurrence, limits of beneficial use, adverse effects, and concentrations observed in the Weiser River basin during the study.

Table 3

Ground-Water Quality

Ground-water samples were collected from 35 wells throughout the area to define current water-quality conditions.

Chemical analyses of water from municipal, domestic, irrigation, and stock wells in the Weiser River basin are given in basic-data table F.

Differences and similarities among selected waters can be illustrated graphically. A distinctive pattern system was suggested by Stiff (1951). His method uses three parallel horizontal axes extending on each side of a vertical zero axis. Concentrations of three cations can be plotted, one on each axis to the left of zero; likewise, three anion concentrations may be plotted, one on each axis to the right of zero. The concentrations are expressed in milliequivalents per liter. The resulting points are connected to give an irregular polygonal pattern (fig. 24). The shape of the resulting polygon is a distinctive identifier of water characteristics. The overall width of the polygon suggests the dissolved-solids concentration of the water. The numerical value of specific conductance above the diagram is a further indicator of the dissolved-solids concentration. The patterns in the upper part of the basin show the ground water to be calcium bicarbonate type with low concentrations of dissolved solids in both the basalt

Basic data table F

Figure 24

and sedimentary-rock aquifers. In the southern parts of the basin, the ground water increases in dissolved-solids concentration but is still generally a calcium bicarbonate type. An exception to this occurs in the vicinity of Cambridge and Midvale, where the water is predominantly a sodium bicarbonate type.

Municipal wells in Council, Cambridge, and Midvale are producing water of "good" quality that is chemically suited for use as drinking water. However, water from municipal well 14N-3W-DDC2 at Cambridge contains concentrations of iron high enough to cause possible staining problems on plumbing fixtures. The municipal wells at Council, Cambridge, and Midvale all withdraw water from the deeper basalt aquifer. Wells 14N-3W-3DDC1 at Cambridge and 13N-3W-8CCC1 at Midvale discharge warm water at 26° and 28.5°C, respectively; this is not unusual because the Weiser River basin has known geothermal systems (Young and Mitchell, 1973). Municipal wells 11N-5W-29BAC1, 11N-5W-29BCD1, and 11N-5W-29BDB1 at Weiser withdraw water from the sedimentary rocks and produce harder water, with dissolved-solids concentrations of 393, 490, and 514 mg/L, respectively. The municipal wells in Council, Cambridge, Midvale, and Weiser were all sampled for bacteria concentrations. At the time of sampling, no bacteria were found in the waters.

Water from wells 14N-1W-10DBA1 and 14N-1W-27ABA1, in Indian Valley, has high concentrations of iron, 2.8 and 1.2 mg/L, respectively. Water from wells in the vicinity of Weiser has fairly high concentrations of dissolved solids. Water from well 10N-5W-17ACCl, south of Weiser on the Snake River flood plain, has the highest concentration of dissolved solids of all wells sampled in the basin (1,150 mg/L). Water from wells 13N-3W-5BCB1, north of Midvale, and 13N-2W-2DCDD2, east of Midvale, has high concentrations of sulfate, chloride, and nitrate, indicating possible contamination. Both wells are downgradient from stock corrals.

Surface-Water Quality

Three water-quality stations were operated during this study along the 100-mi (161-km) stretch of the Weiser River--Weiser River above the mill pond at Tamarack at river mi (94.8 (km 152.5), Weiser River near Cambridge at river mi 50.3 (km 80.9), and Weiser River near Weiser at river mi 15.1 (km 24.3). These stations were sampled monthly from April 1974 to December 1975. The Weiser River near Weiser station has about three samples per year from 1968, which are also included in basic-data table G.

Water in the Weiser River is generally of good chemical quality and suitable for most uses. Figure 25 shows the dissolved-solids concentrations at the three monthly stations on the Weiser River for the period of study.

In a preceding section, "Ground-Water Contribution to Surface-Water Flow," the effect of ground-water discharge on the specific conductance of surface water was discussed. As the proportion of ground-water discharge to the Middle Fork Weiser River increased, the dissolved-solids concentrations; therefore, the specific conductance also increased (fig. 7).

The dissolved-solids concentrations reflect the quality of the two main sources of water to the Weiser River--ground-water inflow and overland flow from snowmelt. Ground-water discharge dominates streamflow in the fall and winter months and causes the dissolved-solids concentration in the

Basic data table G

Figure 25

river to increase to maximums of about 100-120 mg/L. In the spring and early summer, snowmelt runoff is dominant and causes the dissolved-solids concentration to decrease to about 50 mg/L. The station Weiser River near Cambridge receives a greater proportion of direct runoff from snowmelt and precipitation, as can be deduced from the precipitation contours on figure 12. The dissolved-solids concentration of the Weiser River is therefore lower at Cambridge than at the other two stations.

Tributaries to Weiser River

Specific-conductance measurements were obtained monthly during periods of flow throughout the study period (basic-data table H). The tributary streams derive most of their flow from snowmelt, which lasts 1 to 3 months during the spring. The flow for the remainder of the year is mostly ground-water discharge. Samples of low-flow discharge were collected during the summer months of 1974 (basic-data table H). The purpose of collecting low-flow samples was to chemically characterize ground water discharging to stream channels throughout the basin.

Selected water-quality characteristics of the Weiser River and its tributaries are shown diagrammatically in figure 26. In addition, values of specific conductance are given above each diagram. As generally indicated by the width of the patterns throughout the basin, water discharging to the tributary stream channels contains very low concentrations of dissolved solids. Exceptions are in waters discharging to Dixie, Banner, Warm Spring, and Hog Creeks, which have higher concentrations of dissolved solids. These streams, except Warm Spring Creek, receive water from aquifers that are composed chiefly of sedimentary materials. Flow in Warm Spring Creek is primarily from hot spring discharge.

Basic data table H

Figure 26

Water-Quality Conditions in the Weiser River

During a Low-Flow Period

A low-flow study of the Weiser River was made August 20-28, 1974, during a period of little or no precipitation on the basin. The small amounts of precipitation that did fall were not large enough to cause runoff in the basin; consequently, the study was conducted during a period of continuous low flow in the Weiser River. All inflows and outflows were measured. Field measurements included water and air temperatures, specific conductance, pH, and dissolved oxygen. Samples were obtained for the determination of nutrients, which included total nitrite plus nitrate, total phosphorus, and total orthophosphorus.

The data collected during the low-flow study are tabulated in basic-data table I, and locations of sampling sites and discharge-measuring sites are shown in figure 27. Graphical representations of observed and measured parameters (figs. 28 and 29) show the range in values at each site.

Apparent gains from or losses to the ground water shown in figure 27 are small in some reaches. However, the general relation of the surface and ground water is shown. The Weiser River generally gains from ground-water discharge in its upper reach, loses to ground-water recharge in its middle reach, and gains from ground-water discharge in its lower reach.

Basic data table I

Figure 27

Figure 28

Figure 29

Nutrient concentrations in the upper reaches of the Weiser River are low, with some introduction of organic materials near Council and Cambridge. In the lower reaches of the river, nutrient concentrations are high enough to support a large algal population, but because the silt content in the lower reaches of the river masks sunlight, algal growths are not large below Crane Creek.

Specific conductance increased downstream throughout the length of the river from 117 to 247 μ mhos, with exceptions resulting from the inflows from West Fork Weiser River, Middle Fork Weiser River, and Crane Creek, which lowered the specific conductance at the point of inflow. The inflow from Little Weiser River increased the specific conductance, possibly because of dissolved solids being carried by irrigation-return water.

Maximum water temperatures generally increased along the river from 15° to 29°C .

The range in percent saturation of dissolved oxygen changed from 98-88 to 159-83 from Tamarack to above Crane Creek. Below Crane Creek, the percent saturation was approximately 130-90 because of less aquatic growth. Levels of pH remained near 8 from Tamarack to Weiser. Generally, throughout all reaches, pH values paralleled dissolved-oxygen concentrations.

Bacteria associated with fecal materials (table 4) were found in the Weiser River at and below Council, below Cambridge, and at the mouth at Weiser.

Pesticides were not detected in the river during the low-flow period.

Table 4

Suspended-Sediment Yield

Sediment is solid material that originates mostly from disintegrated rocks and soil and is transported by streams in a selective process in which the finer grained and lighter weight particles are removed and carried away by runoff and streamflow. Suspended sediments, therefore, generally contain higher percentages of clay, silt, and organic matter than the soils from which they were derived.

Soil structure and drainage patterns, together with the intensity and temporal distribution of precipitation, determine the susceptibility of a soil to erosion. In areas where precipitation occurs throughout the year, protective grasses, shrubs, and trees develop. In areas of intermittent precipitation, protective plant growth is limited, thus making soils more susceptible to erosion during periods of runoff. Moreover, the removal of protective vegetation and land-surface disturbances by man's activities cause increased soil erosion during runoff periods.

Land use has a strong bearing on the potential sediment yield of an area. Land use in the Weiser River basin (fig. 30), as determined from land-classification maps by the U.S. Department of Agriculture, Soil Conservation Service, includes rangeland, woodland, irrigated crop- and pastureland, nonirrigated cropland, recreation, and urban, in descending order of use.

Figure 30

In the central and southern parts of the basin, range-land is predominant, whereas in the more mountainous northern part of the basin, woodlands predominate. Irrigated crop- and pasturelands are confined to the lowlands and valleys along the Weiser River and its major tributaries. Non-irrigated croplands are mostly adjacent to the irrigated croplands and are restricted to the gentle, rolling terrain of the central and southern parts of the basin.

Sediment transport is generally related to stream discharge and the relations can be depicted by sediment-rating curves. These curves are graphs of sediment load versus stream discharge. The sediment-rating curves presented in figures 31 and 32 were constructed using data given in basic-data table J. The graph for Weiser River near Cambridge (fig. 31) also includes and is partly based on unpublished data from the U.S. Bureau of Reclamation.

Sediment-rating curves were used in conjunction with daily discharges published in U.S. Geological Survey annual surface-water data reports (1974 and 1975) to estimate sediment yields for the Weiser River gaging stations for the study period. These estimates are presented as monthly and annual totals (table 5).

Average annual sediment yields can also be estimated using the sediment-rating curves of figures 31 and 32 in conjunction with streamflow-duration data. Flow-duration

Figure 31

Figure 32

Basic data table J

Table 5

curves of daily flows at selected Weiser River stations are shown in figure 15. Estimated mean annual suspended-sediment transport is about 43,000 tons (39,000 t) at Weiser River near Cambridge and about 97,000 tons (88,000 t) at Weiser River near Weiser (table 6).

Another technique can be used to estimate annual sediment transport past a site having only short or intermittent flow records. This method uses an estimated duration curve developed by a correlation technique. This curve then can be used to estimate average annual sediment yields from sediment-rating curves, as above.

Mean annual suspended-sediment transport at Weiser River near Cambridge using the duration curve for the period of record is about 43,000 tons/yr (39,000 t/yr) (table 6). Mean annual suspended-sediment transport using estimated duration curve is about 56,000 tons/yr (47,000 t/yr), or about 16 percent difference. Mean annual suspended-sediment transport at Weiser River near Weiser using the duration curve for the period of record is about 97,000 tons/yr (88,000 t/yr) (table 6). Mean annual suspended-sediment transport using the estimated duration curve is about 128,000 tons/yr (116,000 t/yr), or about 24 percent difference. Thus, the estimated duration curve technique gives reasonable mean annual sediment yield values within the Weiser River basin. Table 7 is a tabulation of estimated annual sediment yields within the basin.

Table 6

Table 7

The mean annual suspended-sediment transports given in table 7 are average rates of yield over the entire area contributing runoff to a gaging site. Obviously, not all parts of a drainage basin yield sediment runoff at the same rate. However, these rates, when modified by varying land-use patterns, differing degrees of surface slope, variable amounts of precipitation, variations in altitudes of land surface, and personal field observations of sediment-yield characteristics, are helpful in defining suspended-sediment-yield rates from a specific basin. Figure 33 illustrates the distribution of sediment yields for an average year as determined and modified by these criteria. Suspended-sediment yields in the Weiser River basin for an average runoff year range from less than 5 tons/mi² (2 t/km²) in the more heavily vegetated woodland areas to over 500 tons/mi² (200 t/km²) from unirrigated farmlands where plowed hill-sides are allowed to stand fallow, at least during winter months.

Figure 33

Crane Creek Reservoir is located in the southeastern part of the Weiser River basin, has a capacity of 51,700 acre-ft (6.3×10^3 m 3), and is filled by runoff from 242 mi 2 (626 km 2) of generally unirrigated farmlands and sparsely vegetated grazing lands. Suspended-sediment yield from these lands is estimated in the range of 20 to 60 tons/mi 2 (70 to 150 t/km 2) for an average runoff year (fig. 33). Observations of turbid water leaving the reservoir during the irrigation season of 1974 raised the question of how much sediment was being transported to the Weiser River by releases from the reservoir. Sediment samples were obtained August 14, 1974, at the stations Crane Creek near Midvale just below the reservoir, Crane Creek at mouth, Weiser River above Crane Creek, and Weiser River at mouth. These samples were analyzed for particle-size distribution, as well as sediment concentration. The particle-size (fig. 34) analysis showed that 95 percent of the sediment leaving the reservoir was composed of silt- and clay-sized materials. The amount of sediment entering the Weiser River from Crane Creek Reservoir increased the sediment concentration in the Weiser River just below their confluence from 10 to 54 mg/L. From August 1 to October 15 each year, an increase in the sediment load of the Weiser River near Weiser is evident as the releases from Crane Creek Reservoir are increased. Figure 32 shows a change in the sediment-rating curve for

Figure 34

this period to be used for computing sediment load in the Weiser River introduced from Crane Creek Reservoir.

SUMMARY

The largest source of readily available water in the Weiser River basin is surface water, and the principal use of water in the basin is for irrigation. The surface- and ground-water resources in the basin are not closely related, except in areas of surface-water use near Weiser. Therefore, the optimum development and use of the surface water would not greatly affect the ground-water resources, except near Weiser.

The principal aquifers in the Weiser River basin are in the Columbia River Basalt Group and in the overlying Tertiary and Quaternary sedimentary rocks. Ground water occurs under both artesian and water-table conditions in the basalt and is typically confined or semiconfined in the sedimentary rocks, except near Weiser, where water-table conditions are found. The principal source of recharge to the basalt aquifer is precipitation falling on basalt outcrops in the mountains. Recharge to sedimentary-rock aquifers is from infiltration of water from snowmelt runoff, streams, and near Weiser, from infiltration of water from canals and irrigated fields. Yields from both basalt- and sedimentary-rock aquifers are highly variable. Ground-water discharge to streams in the mountains is usually sufficient to maintain year-round streamflow.

Mean annual flow past the Weiser River near Weiser gaging is 1,090 ft³/s (30.8 m³/s), or 788,000 acre-ft/yr (0.97×10^9 m³/yr). Tributary runoff is strongly related to altitude, with maximum flows in the lower altitude tributaries occurring in January, and in the higher altitude tributaries in April and May. Weiser River flows are directly affected by irrigation diversions, especially in the mid- and late summer months.

Ground waters of the basin are generally of "good" quality; that is, they are suitable for present uses. Ground water in the part of the basin above Cambridge contains dissolved-solids concentrations of less than 200 mg/L. The valley-fill areas near Cambridge and Midvale have a similar type of ground water, with dissolved-solids concentrations of about 150 mg/L.

The possible contamination of rural wells by barnyard or septic-tank pollutants is suspected in a few places in the basin. Improper well construction probably permits these contaminants to enter wells.

During low-flow periods, usually late summer, the water quality in the Weiser River deteriorates. Where waters have high temperatures, near 25°C, algal growths are abundant in some reaches between Cambridge and Weiser. Introduction of fecal material at Council, Cambridge, and Weiser during these critical low-flow periods causes high concentrations

of pollution-indicating bacteria, which suggest a possible health hazard.

Suspended-sediment yields in the Weiser River basin range from 5 tons/mi² (2 t/km²) to over 500 tons/mi² (200 t/km²) per year.

RECOMMENDATIONS FOR MONITORING NETWORK

To provide data for management of the water resources of the Weiser River basin, the following network for the monitoring of ground-water-level fluctuations, surface-water flow, and water-quality changes is suggested.

(1) ground-water observation wells: Initiate bimonthly water-level measurements in the following wells completed in the basalt aquifers near or in Fruitvale, Council, Mesa, Cambridge, and Crane Creek Reservoir--17N-1W-15AAC1, 16N-1W-22BB1, 15N-1W-22BAD1, 14N-2W-6DCD1, and 13N-1W-32ADC1; initiate bimonthly water-level measurements in the following wells completed in the sedimentary-rock aquifers near Cambridge, Mann Creek, and Weiser--14N-2W-10BCA1, 12N-4W-31DBB1, and 11N-6W-25CAC1; and continue bimonthly water-level measurements in the following Idaho State observation well completed in the basalt aquifer near Indian Valley--14N-1W-11CCC1, and the Idaho State observation wells completed in the sedimentary-rock aquifers near Council and Midvale--16N-1W-3DDD2 and 13N-4W-12CDC1.

(2) Stream-gaging stations: Continue operation of the gaging stations Weiser River near Weiser and Weiser River near Cambridge to provide streamflow data for the Weiser River; install a gaging station on Crane Creek above the reservoir to provide streamflow data descriptive of hydrologic conditions in the upper Crane Creek area.

(3) Water-quality sampling sites: Randomly sample

individual domestic water-supply systems from wells completed in the sedimentary-rock aquifers near Weiser and Midvale to detect possible water-quality and bacterial changes resulting from localized contaminants; sample the Weiser River at Weiser monthly for chemical and bacterial concentrations to determine the quality of the surface water leaving the basin; sample the Weiser River below Council, Cambridge, and Midvale monthly from July to August for bacteria and nutrients to assess the contaminants entering the river; sample at the station Weiser River near Weiser monthly for suspended-sediment concentrations to determine annual suspended-sediment yield of the basin and of Crane Creek Reservoir, and sample Crane Creek and South Fork Crane Creek for suspended-sediment concentrations during high-flow periods above the reservoir to determine the amount of sediment entering Crane Creek Reservoir.

TABLE I - Capacities of major reservoirs in the Weiser River basin.

Reservoir name	Owner	Stream	Active ¹ capacity (acre-feet)	Total capacity (acre-feet)	
Lost Valley	Lost Valley Reservoir Company	Lost Creek	10,100	10,100	
C. Ben Ross	Little Weiser River Irrigation District	Little Weiser River	7,600	7,800	
Mann Creek	U.S. Bureau of Reclamation	Mann Creek	11,000	13,000	
Crane Creek	Crane Creek Reservoir Administration Board	Crane Creek	52,000	52,000	
Totals			80,700	82,900	

Data from U.S. Bureau of Reclamation, 1971

1 - Reservoir capacity available for release

2 - Reservoir not located on river

To convert acre-feet to cubic meters multiply by 1,233

Table 2 Water rights (decrees, licenses, and permits) in
the Weiser River basin = April, 1974. Data
furnished by Idaho Department of Water Resources

Source	Rate of diversion allowed by rights, cubic foot per second			
	Decrees	Licenses	Permits	Total
Weiser River	259	145	47.2	451
West Fork Weiser River	1.83	0	0	1.83
East Fork Weiser River	19.3	0	0	19.3
Middle Fork Weiser River	73.7	0	0	73.7
Beaver Creek	0	1.05	0	1.05
Gaylord Creek	0	5.2	6.4	11.6
Warm Spring Creek	0	1.8	2.0	3.8
Mill Creek	13.0	0.7	0	13.7
Hornet Creek	18.9	1.2	0.53	20.7
Lester Creek	0	0.48	0	0.48
Cottonwood Creek	19.6	0.6	0	20.4
Johnson Creek	0	1.5	0	1.5
Goodrich Creek	0.28	12.9	0	13.2
Cow Creek	1.44	1.38	0	2.82
Rush Creek	23.0	10.0	0	33.0
Spring Creek	0.95	0	0.1	1.05
Pine Creek	24.5	4.02	0	28.5
Dixie Creek	0	1.2	0	1.2
Keithly Creek	15.9	2.1	0	18.0
Bonner Creek	0	0	2.4	2.4
Sage Creek	6.96	0.06	14.0	21.0
Deep Creek	0	0	1.0	1.0
Pole Creek	0	0	2.4	2.4
Thousand Springs Creek	0	1.6	0	1.6
Hog Creek (near Crane)	0	0	0.8	0.8
Mill Creek (near Crane)	0	2.4	0	2.4
Crane Creek (a)	4.67	32.3	12.5	49.5

Table 2 - continued

Source	Decrees	Licenses	Permits	Total
Cove Creek	0	1.2	3.0	4.2
Mann Creek	0	0	47.3	47.3
Monroe Creek	ALL	28.1	5.12	33.2
Jenkins Creek	0	21.1	0	21.1
Scott Creek	0	0.62	6.4	7.02
Hog Creek	0	0.6 ^b	0	0.64
Miscellaneous Streams	4.42	33.7	38.6	76.7
Miscellaneous Springs	<u>0</u>	<u>4.6</u>	<u>12.7</u>	<u>17.3</u>
Total	487	316	202	1005

a Includes both North and South Forks of Crane Creek

b Monroe decrees not shown in total

c Water rights given in acre-feet - converted to c.f.s. assuming a 180 day flow period.

To convert cubic feet per second to cubic meters per second multiply by 0.028

Constituent	Significance	Concentration of Normal occurrence	Limits for Domestic Use	Adverse Effects	Unusual Concentration May Indicate	Concentrations Observed in Sampled Water River Basin water	Remarks
Nitrite plus Nitrate as Nitrogen ($\text{NO}_2 + \text{NO}_3 = \text{N}$)	Plant nutrient	0.10 to 10 mg/l	10 mg/l	Infants may develop temporary blood disorder, excessive algae growths	Organic wastes or excessive fertilization	0. to 78.0 mg/l	Excessive concentrations may indicate possible organic pollution
Total Phosphorus as Poly-phosphate (P)	Plant nutrient		1 mg/l	Excessive algae growths	Organic pollution	0.01 to .99 mg/l	
Dissolved solids measure of mineralization of water		50 to 1,000 mg/l	500 mg/l	Cathartic effect on humans loss of soil permeability	Excess Salinity	50 to 1,150 mg/l	
Percent Sodium Percent sodium among the total cations in milliequivalents per liter. Relation of cation exchange rate water and soil ions.			50 percent			15 to 25 percent	
SAR (Sodium Absorption Ratio)						0.2 to 1.5	
Specific conductance Estimate of dissolved solids		50 to 1,000 microhos per cm.	700 microhos per cm.			50 to 1,810 microhos per cm.	Easily measured
Temperature (°C)	Higher ground water temperatures indicate deeper water circulation or thermal activity			Surface water higher temperatures less dissolved oxygen	Thermal pollution, association with thermal water	0° to 28.5 °C	
Dissolved Oxygen (DO)	In surface water required to sustain aquatic life			loss of aquatic growth and reproduction	Low concentrations in surface water indicate pollution	6.4 to 13 mg/l	
Indicator Bacteria (fecal coliform)					Fecal pollution	0 to 940 col. per 100 ml.

**UNIVERSITY OF UTAH
RESEARCH INSTITUTE
EARTH SCIENCE LAB.**

Basic-data table A Records of wells in the Weiser River basin

Scutellaria = *Scrophularia* *Scutellaria*

well finish; F-general packed with perforations;
G-open end; P-perforated; S-wire
screen; T-some points; X-open
hole.

water level: (2) feet above land surface;
R - reported.

Principal Aquifer: OTS- Cenozoic and Tertiary
stratigraphic deposits; Tern Basinity at
Colombian River Coast Cong.

Use of winter : H-donstration ; I- irrigation
P- public supply ; S- stock
Unusued

Remarks: Log-Dieter's log variable

QW- Chemical analysis of water available (basic-dissoluble F)

W.L.	Number	Date of Completion	Depth to bottom (feet)	Casing and casing thickness (inches)	Well Finish	Date last bore and surface (date)	Water level (feet) and surface (date)	Hydrogeal Aquitard (yes/no)	Depth to Principal Aquifer (feet)	Reported Discharge (cfs)	Ground water (feet)	Use of water (none, irrigation, etc.)	Remarks

To convert cubic feet per second to cubic meters per second multiply by 0.02832.

Basic-data table F Chemical analyses of water from selected wells and springs in the Weiser River basin
 (chemical constituents in milligrams per liter except where noted)

Water level: R - reported

Use of water: I - irrigation; P - public supply;

Principal aquifer: QTs - Quaternary and
 Tertiary sedimentary deposits

S - stock; U - unused.

Ter - Basalts of
 the Columbia River
 Basalt Group

Well Number	Groundwater Elevation (ft.)	Principal Aquifer	Use of water	Date of sample	Dissolved silica (SiO ₂) (mg/l)	Dissolved silicate minerals (mg/l)	Dissolved carbonate (CaCO ₃) (mg/l)	Dissolved sulfate (SO ₄) (mg/l)	Dissolved chloride (Cl ⁻) (mg/l)	Magnesium (Mg) (mg/l)	Nitrate as NO ₃ (mg/l)	Dissolved nitrite (NO ₂) (mg/l)	Dissolved fluoride (F ⁻) (mg/l)	Dissolved boron (B) (mg/l)	Dissolved strontium (Sr) (mg/l)	Concentrations water samples	Ferrous sulfide (mg/l)	Sodium adsorption ratio (mg/l)	Specific conductance (µmhos/cm)	pH	Temperature (°C)	Dissolved iron (Fe) (mg/l)	Dissolved uranium (U) (mg/l)

TABLE 6

Mean annual ^{suspended} sediment transport using 45 days of flow duration, or
and sediment rating for Weiser River near Cambridge and near Weiser

Days of high flow	Percentage of yearly time	Average percent	Q_w from duration curve (in cubic feet per second)	Q_s Tons per day from figures 31 and 32.	Q_s days (in tons)
Weiser River near Cambridge					
1	0 - .27	.135	5,500	6,150	6,150
2	.27 - .82	.54	4,400	3,430	4,860
4	.82 - 1.92	1.37	3,600	2,030	8,110
8	1.92 - 4.11	3.02	2,850	1,100	6,300
15	4.11 - 8.22	6.16	2,200	558	8,370
<u>15</u>	<u>8.22 - 12.33</u>	<u>10.28</u>	<u>1,710</u>	<u>316</u>	<u>4,740</u>
45 days	12.33 %			43,040	Tons per year
Weiser River near Weiser				(Fig. 32)	
1	0 - .27	.135	10,800	20,320	20,320
2	.27 - .82	.54	7,600	8,260	16,520
4	.82 - 1.92	1.37	5,850	4,230	16,920
8	1.92 - 4.11	3.02	4,500	2,160	17,280
15	4.11 - 8.22	6.16	3,480	1,120	16,800
<u>15</u>	<u>8.22 - 12.33</u>	<u>10.28</u>	<u>2,770</u>	<u>620</u>	<u>2,300</u>
45 days	12.33 %			97,440	Tons per year

To convert cubic feet per second to cubic meters per second multiply by 0.02832
To convert tons to metric tonnes multiply by 0.9072.
