INTRODUCTION

The Earth Science Laboratory Division of the University of Utah Research Institute has the task (Technecon, 1980) of determining generic resource types for all hydrothermal resources in the United States for input to an economic decision-making model (Cassel et al., 1979). Pursuant to this task is the definition of several variable resource characteristics that will distinguish each generic type. Other characteristics of hydrothermal resources are considered common among the generic types and either are not considered here (no economic impact) or are considered but are treated as invariant (constant economic impact). A wide spectrum of resource characteristics is considered in order to include resources for both electric power generation and direct heat utilization.

GENERIC RESOURCE CHARACTERISTICS

Assumptions

Several assumptions are necessary to permit a realistic representation of all known and undiscovered hydrothermal resources by a limited number of generic types. These assumptions are as follows:

1. Data from known hydrothermal systems can be selectively extrapolated to both identified and unidentified systems that lack such data;
2. Mean reservoir temperatures, known and estimated, as published in USGS Circular 790 (Muffler, 1979), apply to the entire population of hydrothermal resources;
3. The selected generic resource characteristics included are sufficient to describe all essential criteria for a valid economic decision-making process; and

4. Resource models developed from known data or developed a priori can be used to predict discoveries.

Characteristics

Cassel et al., (1979) have determined from previous work that the resource characteristics listed in Tables 1 and 2 are important in economic decision-making processes leading to development of hydrothermal resources. As a first step in our study, resource and exploration characteristics and data were compiled for the important, known hydrothermal resources in the world. From this data base, typical ranges of values were determined for each resource characteristic. Ranges of values for selected characteristics were then tested in the economic model (Cassel et al., 1979) for model sensitivity to these ranges. The results of this sensitivity analysis (Cassel, 1980; Appendix I) were used to determine a smaller list of characteristics whose values affect the economic model most. This list is given as Table 1, and the ranges in values were used to characterize generic hydrothermal resource types.

Other resource characteristics were relegated to a list of constant or dependent characteristics or were dropped from further consideration because of lack of significant economic impact in terms of the present study. Estimated values for the constant or dependent resource characteristics are included in Table 2. For each constant resource characteristic either the model is relatively insensitive and an average value can be used or the model is sensitive to the particular characteristic but the characteristic does not vary significantly. Each dependent resource characteristic can be determined

from other parameters of the model, and so no independent estimate is required.

The resource characteristics listed in Tables 1 and 2 were reviewed at the Denver meeting of the Hydrothermal Market Estimates Task Force on April 22 and 23, 1980. A few changes in these characteristics had been made from those used by Cassel et al. (1979) in earlier studies. The most significant change is the inclusion of pumping in the model. A second significant change that was then anticipated, namely the inclusion of time-varying parameters such as drawdown of reservoir pressure and temperature with time with a compensating increased pump rate with time, is not shown in Table 1 because the economic model cannot incorporate these data.

Table 3 contains the complete list of resource parameters that were investigated for this study.

GENERIC RESOURCE TYPES

The resource characteristics in Table 1 are believed to provide sufficient range to develop generic categories for both electric power generation and direct heat applications. The presence of a range category in Table 1 does not imply that resources exist within that range. A maximum of 9408 different generic resource types are possible from the number of range values in Table 1. This study has identified a total of 85 generic resource types thought to be representative of all known and undiscovered hydrothermal resources. These generic resource types are listed in Table 4 and details are presented in Appendix II. The data shown on each form in Appendix II have

been derived so far as possible from consideration of known resources. However, these data may not be entirely representative of the geothermal resource base since most recent geothermal exploration has been performed by private industry, and most of the resulting information is proprietary.

The generic type is expressed as a number such as 441351, and is derived from the range numbers shown in Table 1 by listing in order the range number for the following characteristics: temperature, unpumped flow rate, brine contamination index, well costs, pumped flow rate, and maximum producible acreage. Thus generic type 441351 has moderate temperature (250-300°F), moderate unpumped flow (200-400 x 10³ lbs/hr), low salinity (<2000 ppm TDS) fairly low well costs (\$0.5M - \$1.0M), a high pumped flow rate (to 400-600 x 10³ lbs/hr), and a producible acreage of less than 10,000 acres.

A number of assumptions have been made in selecting the appropriate range numbers defining a generic resource type. Moreover, estimates of some resource characteristics can be made with greater confidence than can others since there are few data available for some of the resource characteristics considered. A discussion of these assumptions and the varying levels of confidence associated with estimating resource characteristics is given below.

Well-Head Temperature. In general, the confidence level for the temperature data is fairly high. Well-head temperature values are based upon geothermometer estimates (Muffler, 1979) or, where available, from measured down-hole temperatures. A comparison of measured down-hole temperatures with temperatures estimated from geothermometry suggests that, at least at high temperatures, geothermometers provide a fairly reliable estimate of reservoir temperature.

The minimum, most likely and maximum values noted for well-head temperature do not reflect variation about a mean. Rather, these temperatures represent the actual variation of temperature at a given site as known or inferred from measured temperatures or geothermometer estimates. The most likely temperature listed is the actual measured down-hole temperature where available. For systems with no bottom-hole temperature-data, the most likely temperature value is selected from the most reliable geothermometer estimate for the system. The most likely temperature value determines selection of the temperature range number.

Unpumped Well Flow Rate. The confidence level for this parameter is considerably less than that for well-head temperature. Flow rates are known only in systems with production test data. Flow rates for systems with no or limited production test data have been estimated from the flow rates known in geologically similar systems. It should be noted, however, that flow rates within a given system are variable and reflect the selection of a successful drilling site and the use of appropriate drilling and completion techniques to allow maximum obtainable flow. Therefore prediction of flow rates is very difficult.

The value estimated for the most likely unpumped flow rate is used to establish the range number. In systems for which flow data are available, the minimum, maximum and most likely unpumped flow rates reflect the actual flow rate variation for these systems. In systems with no production data the minimum and maximum flow rates were selected so as to fall within the range number determined by the value for most likely unpumped flow rate.

Brine Contamination Index. In general the fluid chemistry of most geothermal systems is known with some confidence. Thus the values selected for brine contamination index are probably fairly reliable. In most cases higher temperature fluids contain more dissolved solids than lower temperature fluids. However, some low- to moderate-temperature geothermal fluids derived from aquifers within deep sedimentary basins may be fairly saline.

Producer Well-Cost. Well costs are expressed in 1978 dollars per agreement with T.A.V. Cassel. Actual well cost minimum, maximum and most likely values are given for systems for which they are known. All other well costs were estimated using the data from Chappell et al. (1979) and were checked with the well-cost analysis provided by Lawford (1980). In this case the minimum and maximum well costs were selected so as to fall within the range number determined by the value for most likely well cost. Drilling costs are fairly well known, resulting in a fairly high level of confidence for producer well cost, assuming that our perceptions of target drilling depths are accurate.

Pumped Well Flow Rates. The discussion of availability of only very limited data, selection of minimum, maximum and most likely values, designation of range number, and level of confidence for unpumped flow rate also applies to pumped flow rate. Several additional assumptions were made in determining pumped flow rate:

1. In systems with high unpumped flow rates, pumping will not be necessary. This is particularly true of high-temperature resources which commonly flash under reduced pressure, resulting in higher

unpumped flow rates than for lower-temperature systems. Thus the range numbers for unpumped and pumped well flow rates are the same in this case. In addition, most present pumps cannot tolerate temperatures in excess of 350°F.

2. For systems with moderate unpumped flow rate, pumping will increase the flow by one range number. In systems with low unpumped flow rates pumping will increase the flow by one to two ranges.
3. Systems with no flow have not been considered since they will not be economic.

Maximum Producible Acreage. Information on maximum producible acreage was available for only a few systems. In most cases estimates were made on the basis of geologic setting. The conceptual model for Basin-and-Range type, fault-controlled systems suggests that these resources are site-specific. It was thus assumed that the 99% confidence area was very limited and generally restricted to no more than 1000 acres. The 50% confidence zone averages about 3200 acres and the 1% confidence level is a step out to about 6400 acres. In contrast, the 99% confidence level for a resource controlled by an aquifer in a deep sedimentary basin is essentially infinite, since a properly drilled and completed well drilled anywhere into the hot aquifer has an excellent chance of production. To reflect these areal differences when all other resource characteristics are identical, we have used two areal generic types, one for restricted systems of generally less than 10,000 acres, and the other for larger systems.

Total Expected Finding Costs. Two different exploration cost constants were selected for electric and non-electric exploration sites. Based upon available geothermal exploration case histories (Ward, 1977; Ward et al., 1979), electric exploration costs are assumed to be \$6 million per site, and non-electric exploration costs are assumed to be \$1 million per site.

PRELIMINARY INFORMATION

April 7, 1980

Dr. P. Michael Wright, Associate Director
University of Utah Research Institute
Earth Science Laboratory
420 Chipeta Way (Suite 120)
Salt Lake City, UT 84108

Dear Mike,

Enclosed are the results of parametric sensitivity evaluations performed by Technecon to assist UURI with generic geothermal resource characterization. Ten parameters were tested, as defined on the attached page titled, "Definition of Resource Parameters".

The basecase for these evaluations is the 100 megawatt level of development at a resource with characteristics similar to the East Mesa KGRA. This basecase was selected because it is neither an extremely high quality nor an extremely low quality resource, and because the 100 megawatt level of development is not heavily encumbered with front-end resource finding costs (as is the initial 50 megawatt level) nor is it hampered by a high level of uncertainty (as are much larger levels of development).

Each of the ten parameters was tested for its effect upon the Expected Utility of the basecase. Expected Utility, as discussed in our report DOE/RA/4713-1, is a measure of the attractiveness of hydrothermal ventures as perceived by investment decision makers within the resource industry. It incorporates measures of capital efficiency, project magnitude, duration of investment exposure and risk of loss into a single value.

Each of the ten enclosed graphs includes a supplementary curve showing the probability that the Expected Utility of the geothermal venture (EU_G) is greater than or equal to the Expected Utility of the firm's alternative investment (EU_A). This may be interpreted as the likelihood that the geothermal venture will be preferable to a firm's alternative and it accounts for idiosyncratic differences in utility preceptions within the resource industry as well as for differences in the quality of investment alternatives.

Based upon these results, and upon discussions in your offices on March 17th and 24th, the following conclusions are drawn:

Dry Hole Fraction. Unless it is expected to be greater than 0.2 during developmental drilling (i.e. *after* confirmation), sensitivity appears low therefore it may be excluded from generic characteristics.

Initial Redrill Fraction. Sensitivity appears low therefore exclude from generic characteristics.

Producer/Injector Ratio. If it is expected to vary significantly from one resource to another, sensitivity is significant therefore include it in generic characteristics. Perhaps it can be fixed at 2?

PRELIMINARY INFORMATION

P. Michael Wright, UURI

April 7, 1980 (P.2)

Replacement Redrill Fraction. Sensitivity is low therefore exclude from generic resource characteristics.

Salinity Index. Sensitivity is significant therefore include in generic resource characteristics. Results indicate that the five-point index used previously (0,1,2,3,4) can be simplified to a two-point index (i.e. low salinity and high salinity). See also the discussion for well life below.

Spare Well Fraction. Sensitivity is significant; however, this fraction may be dependent upon industry reliability concerns moreso than resource characteristics and may, therefore, be excluded from generic resource characteristics.

Temperature. Sensitivity is significant therefore include in generic resource characteristics. Results indicate decreasing marginal sensitivity with increasing temperature which permits wider temperature bands for generic classification at higher temperatures. Resources may be generically grouped in temperature bands of 300-320F, 320-350F, 350-400F, and greater than 400F.

Well Cost. Sensitivity is significant therefore include in generic resource characteristics. Results indicate that uniform increments of \$200,000 may be used to generically group resources, i.e. \$200-400K, \$400-600K, \$600-800K, etc. Both well depth and type of geology (i.e., igneous or sedimentary) are incorporated into well cost according to Figure 2-2 on page 2-7 of Report DOE/RA/4713-1, therefore these two characteristics may be excluded from generic characteristics.

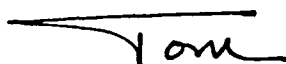

Well Flow. Sensitivity is significant therefore include in generic resource characteristics. Results indicate decreasing marginal sensitivity with increasing well flow which permits wider flow rate bands for generic classification at higher flow rates. Resources may be grouped generically in well flow bands of less than 250,000 lbs/hr, 250,000-300,000 lbs/hr, 300,000-400,000 lbs/hr, 400,000-700,000 lbs/hr, and greater than 700,000 lbs/hr.

Well Life. Significant sensitivity appears for well lives of less than five years. If the Salinity Index may be used as the determining factor for well life, these two characteristics may be coupled such that a low salinity implies a well life of greater than five years, while a high salinity implies a well life of two to five years. If this is possible, Well Life need not appear as an explicit generic resource characteristic.

Other important characteristics which were not tested but which we have discussed include well spacing, probabilistic resource size, and probabilistic resource performance (e.g., decline of temperature and flow) over time. If, for the purposes of the analysis at hand, well spacing may be fixed at 40 acres per well, I would suggest that we do fix it. Size and performance characterizations will have to be discussed in meetings within the next few weeks.

If you have any questions about this sensitivity evaluation, please give me a call.

Regards,

Thomas A.V. Cassel, Ph.D., P.E.

DEFINITION OF RESOURCE PARAMETERS

Dry Hole Fraction. Fraction of total production wells drilled during resource development (i.e. *subsequent to* resource confirmation) which are abandoned as nonproducing.

Initial Redrill Fraction. Fraction of successful production wells drilled during resource development which must be redrilled to achieve satisfactory producibility.

Producer/Injector Well Ratio. Ratio of number of production wells to reinjection wells in a well field.

Replacement Well Fraction. Fraction of replacement production wells which are redrilled old wells rather than new wells.

Salinity Index. An index which, as used in Report DOE/RA/4713-1, ranges from 0 for uncontaminated, low salinity geothermal brines to 4 for highly contaminated, highly saline geothermal brines. It is used to adjust well field operating and maintenance costs.

Spare Well Fraction. Fraction of total successful production wells which represent spare standby production capacity as opposed to active production capacity.

Temperature. Well head temperature of geothermal fluid in degrees F.

Well Cost. Total cost of a successful production well including drilling costs, casing and well head equipment. Expressed here in 1978 dollars.

Well Flow. Production rate of a successful well expressed in thousands of pounds of geothermal fluid per hour.

Well Life. Life time of successful production wells until replacement is required. Expressed in years.

Total Expected "Finding Costs" (Including Expenses on Unretained Land)
 Up To and Including Discovery of One Producible Well (1980 \$): 1,000,000

COMMENTS

Aquifer in buried volcanic rocks, large flow rates. May apply to Eastern Washington, too. Producible acreage may be large and dependent upon User location.

 Maximum 1,000,000

Attainable Well Flow Rate with Pumping (10³ lbs/hr)²: Minimum 400
 Most Likely 500
 Maximum 600

Maximum Produccible Acreage²: @ 99% Probability > 10,000
 @ 50% Probability _____
 @ 1% Probability _____

Total Expected "Finding Costs" (Including Expenses on Unretained Land)
 Up To and Including Discovery of One Produccible Well (1980 \$): 1,000,000

COMMENTS

Saline portions of buried sedimentary aquifers like the Madison. Produccible acreage unlimited; must be colocated.

GENERIC CATEGORY NO. 1 4 1 2 3 2 1

TYPE Fault controlled
general
Buffalo Valley

Well-Head Temperature (°F)^{2,3}: Minimum 250
 Most Likely 275
 Maximum 300

Unpumped Well Flow Rate (10³ lbs/hr)^{2,3}: Minimum 0
 Most Likely 30
 Maximum 50

Brine Contamination Index (0, 1 or 2)^{2,4}: 1

Producer Well Cost (1978 \$)^{2,5}: Minimum 500,000
 Most Likely 750,000
 Maximum 1,000,000

Attainable Well Flow Rate with Pumping (10³ lbs/hr)²: Minimum 50
 Most Likely 75
 Maximum 100

Maximum Producible Acreage²: @ 99% Probability 640
 @ 50% Probability 1500
 @ 1% Probability 5000

Total Expected "Finding Costs" (Including Expenses on Unretained Land)
 Up To and Including Discovery of One Producible Well (1980 \$): 1,000,000

COMMENTS

Fault controlled, widespread occurrence
