Abstract

The simulator SHAFT79 of Lawrence Berkeley Laboratory has been applied to field-wide distributed parameter simulation of the vapor-dominated geothermal reservoir at Serrazzano, Italy. Using a three-dimensional geologically accurate mesh and detailed flow rate data from 19 producing wells, a period of 15.5 years (from 1959 to 1975) has been simulated. The reservoir model used is based on field measurements of temperatures and pressures, laboratory data for core samples, and available geological and hydrological information. The main parameters determined (adjusted) during development of the simulation are permeabilities and much of the initial conditions.

Simulated patterns of pressure decline show semi-quantitative agreement with field observations. Field pressures decline overall somewhat more rapidly than predicted in the simulation. It is concluded that (i) the interface between overlying steam cap and deeper boiling aquifer remains stationary during exploitation; (ii) the aquifer boils approximately uniformly throughout in response to production.

Furthermore, the simulation suggests that (iii) there is cold water recharge and/or incomplete heat transfer from the rock due to fractures in the margins of the reservoir, and (iv) some steam flowing to the main well field originates from deep fractures rather than from boiling in the two-phase zones modeled.

Simulation methodology and ambiguity of parameter determination is discussed.

1. Introduction

Serrazzano geothermal reservoir is one of the distinct zones of the extensive geothermal area near Larderello in central Tuscany, Italy. Natural manifestations and utilization of steam and hot water from shallow holes in this region have occurred for centuries. Deep drilling was begun after 1930, and since 1939 electric power has been generated at Serrazzano from geothermal steam (with an interruption in World War II, when the wells were destroyed).

We have developed a distributed-parameter simulation of the performance of Serrazzano reservoir from 1959 to 1975. To our knowledge, no such simulation has ever been attempted for a producing vapor-dominated geothermal reservoir. Serrazzano was chosen as a case study for developing and evaluating the methodology for two reasons: (1) detailed production data and much geological and hydrological information is available for the reservoir; (2) for environmental reasons surface disposal of produced brines is no longer acceptable in Italy, and numerical studies are needed to aid in developing an appropriate injection program.

The numerical simulations presented in the present paper were carried out with a computer program called SHAFT79. This program was developed at Lawrence Berkeley Laboratory, and is briefly reviewed in Chapter 2. Data base and elements of a conceptual model for Serrazzano are discussed in Chapter 3. Subsequently we explain the method used in developing a history match simulation, and present results for our current "best" model of Serrazzano reservoir.

2. The Simulator SHAFT79

SHAFT79 solves coupled mass- and energy-transport equations for two-phase flow in a porous medium, using an integrated finite difference method. This method allows a very flexible one-, two-, or three-dimensional description of reservoirs, and is easily applicable to irregular shapes and geological features. Methodology and applications of SHAFT79 have been discussed in References 1-3. The main assumptions and approximations can be summarized as follows: (1) Geothermal reservoirs are approximated as systems of porous rock saturated with one-component fluid in liquid and vapor form. (2) Porosity can vary with temperature and pressure, with all other rock properties being constant. (3) Liquid, vapor, and rock matrix are in local thermodynamic equilibrium, i.e., at the same temperature and pressure, at all times. (4) Capillary pressure is negligible.

SHAFT79 includes an accurate description of thermophysical properties of water substance, based on the steam table equations as given in Reference 4. Time is discretized fully implicitly, and the coupled non-linear finite difference equations for mass- and energy-transport are solved simultaneously, using Newton/Raphson iteration. The linear equations arising in the iteration are solved with an efficient sparse solver.⁵

Accuracy of the program has been verified by comparison with numerical simulations published in the literature, and by comparison with the quasi-analytical similarity solution method developed by O'Sullivan.^{6,7} Table 1 summarizes the performance of SHAFT79 in simulating our present "best" model of Serrazzano geothermal reservoir on LBL's CDC-7600 computer.

3. The Data Base

At the present time, Serrazzano field has 19 producing wells and 18 wells which are shut in because they are dry or nearly dry. The produced fluid is

approximately 96.5% superheated steam, and 3.5% non-condensable gases (mainly CO₂). Liquid water has never been encountered at Serrazzano. However, mass balance considerations demonstrate convincingly that most of the fluid reserves in Serrazzano are in place in liquid form.⁸ From the drill logs it has been possible to identify the permeable strata of the reservoir, and to map the geometry of the system.^{9,10} The reservoir is an anticlinal horst-and-graben structure, with thickness varying from some ten meters near the intensely fractured structural high to more than 500 meters in areas with thick layers of "evaporite" rocks (see Figure 1). The "evaporite" complex consists of highly permeable and porous anhydrite, limestones, and radiolarites. The location of impermeable boundaries is somewhat open to question.

Formations underlying the structural high may have non-negligible permeability and porosity. Fractures are known to play an important role in fluid transport in Serrazzano.^{11,12} It appears possible that significant amounts of steam are brought through fractures into the main reservoir from great depth (> 2 km).

Geochemical and hydrological work has shown that Serrazzano field is a rather isolated section of the Larderello geothermal region; no significant recharge is believed to occur.¹³

Average properties of the rock matrix are subject to large uncertainty. Laboratory tests on cuttings have given consistent values for specific density, specific heat, and heat conductivity. However, average porosity and permeability cannot be determined from core samples on a laboratory scale. These parameters are very poorly known. A few drawdown- and buildup-tests have been conducted in the past, from which a rough picture of the kH-distribution has been inferred.^{14,15} Interpretation of these tests is questionable due to 2-phase conditions in parts of the reservoir.

Wellhead temperature and pressure measurements in flowing wells, and pressure measurements in shut-in wells, provide a basis for determining average thermodynamic conditions in the reservoir. Interpretation of these data is complicated by substantial variations on a local scale, sometimes due to deep fractures, sometimes due to shallow cold aquifers.

Operating conditions in Serrazzano approximate production with constant pressure $p \approx 5$ bars. Many wells have rather small flow rates, and estimation of downhole conditions is uncertain because of unknown and possibly large effects from heat losses to shallow aquifers.⁸

Important work on average pressure distributions in Serrazzano was done by Atkinson et al. (ref. 16). Using somewhat subjective judgment in evaluating field data with their sometimes large fluctuations and local variations, these authors were able to construct several contour maps of average reservoir pressures between 1960 and 1975. These pressure maps, when combined with temperature data, show that superheated conditions prevail throughout the main well field, near the structural high.

No direct information exists regarding the distribution of pore water in the reservoir. A rough hint is available from a conceptual model of Serrazzano as developed by Weres et al.^{17,18} Postulating hydraulic continuity with surrounding aquifers, and using a plausible value of $T = 275^{\circ}\text{C}$ for initial (pre-exploitation) reservoir temperature at depth, the steam/two-phase interface is estimated near 500 m depth.

Positions, producing horizons, and time-dependent flow rates are known for all wells.

In summary: Although much data and qualitative information is available for Serrazzano, the data base falls very much short of the detailed and

complete definition required as input for distributed parameter simulation. Moreover, available data reflect actual field conditions to varying degrees, and are subject to various degrees of confidence. As indicated in Table 2, the most significant deficits with regard to data availability exist in the areas of permeability, distribution of pore water, and porosity. Partially unavailable or uncertain are data defining geometry and boundary conditions of the reservoir, and the detailed distribution of temperatures and pressures.

4. Method of Simulation

The simulation is carried out using the geologically accurate mesh as developed by Weres (ref. 18). Figure 1 gives an areal view of the reservoir, with the positions of the geological cross-sections employed in the mesh generation indicated by straight lines labeled A to Z. Figure 2 shows the computer-generated mesh in two different (rotated) views. The mesh represents a reservoir that is a curved thin sheet approximately 1 km from top to bottom, and areally covers about 25 km². It has 234 polyhedral elements with 679 polygonal interfaces between them. There are up to 10 interfaces per element.

Our initial attempts to model the pre-exploitation phase were soon abandoned when it became apparent that the almost complete lack of data would leave us with a multitude of rather meaningless parameter choices. Subsequently, we endeavored to model the post-1959 period, for which rather detailed field data are available.

The data (Table 2) have to be grouped into those which are provided as input to the simulation, and those against which simulated results are compared. The division between the two groups is to some extent arbitrary. We noted before that operating conditions in Serrazzano approximate production with

constant (well head) pressure. For modeling purposes, this could be imposed as a (mathematical) sink condition. The objective then would be to match observed production flow rates.

We chose a different approach, which makes a more sensitive use of the observed flow rate data. (These data are measured with good accuracy.) Namely, we impose observed flow rates on the simulated reservoir model. The task of the history match simulation then becomes one of (i) sustaining the observed flow rates over the period from 1959 to 1975, for which production data are available, and (ii) doing so under conditions of relatively mild pressure fluctuations near the main well field.

The history match simulation proceeds in trial-and-error fashion. We make certain assumptions for those parameters which are not well known, or are unknown, compare simulated field performance with observed performance, and then modify our parameter estimates so as to reduce discrepancies between simulated and observed performance. The limited availability of data (see Section 3) confronts us with a multitude of choices. It would appear that one could invoke a large variety of assumptions ad hoc, which may not be too meaningful, yet could not be refuted. The actual situation is, however, not anywhere near that ambiguous. The seemingly rather trivial requirement of sustaining observed flow rates at nearly constant pressures turns out to be very restrictive, due to the long duration of the simulation (15.5 years). The main well field near the structural high contains superheated steam, and therefore has a rather small mass content. The mass produced over 15.5 years is several hundred times larger than the mass in place in the main well field. Only through very subtle fine-tuning of certain parameters was it possible to avoid a premature catastrophic decline of pressures in the

main well field. Table 2 summarizes the handling of the various parameters during development of the history match.

Most important among the adjustable parameters is the permeability distribution. It determines the "dynamic" response of the reservoir; i.e., the way in which time-dependent production rates $q(t)$ give rise to time-dependent pressures $p(t)$. The permeability along the 1-phase flow path determines the short-term (days or weeks) "elasticity" of well field pressure response to fluctuations in production rates. Permeability distributions in the two-phase (boiling) region determine the extent to which pressure at the two-phase/steam interface can be maintained over periods of substantial depletion (years).

Under favorable circumstances, boiling rates away from the interface can be sufficiently large (equal to or larger than at the interface) to supply enough hotter steam to sustain temperature (hence pressure) at the interface. Then, the interface remains approximately stationary and at approximately constant pressure, while pressures decline away from the interface at the margins of the reservoir. The maps of average pressures as developed by Atkinson et al. (ref. 16) suggest that this type of behavior is present in Serrazzano.

A pattern of depletion with approximately stationary two-phase/steam interface at approximately constant pressure can prevail as long as the reserves of liquid water last. Reservoir performance during this period depends little on ultimate fluid reserves, and the simulation is not very sensitive to variations of those parameters which determine ultimate fluid reserves. These are mainly porosity ϕ and vapor saturation S in the two-phase zone. Therefore we have kept ϕ constant at a "best guess" of 10%.

Initial vapor saturation was chosen as follows. We compute relative

permeabilities from a version of Corey's equations:

$$k_{\text{steam}} = \begin{cases} (2r-S) S^3/r^4 & \text{for } S \leq r \\ 1 & \text{for } S \geq r \end{cases}$$

$$k_{\text{liquid}} = \begin{cases} (r-S)^4/r^4 & \text{for } S \leq r \\ 0 & \text{for } S \geq r \end{cases}$$

with the residual immobile water saturation taken as a somewhat arbitrary $1-r = 40\%$.

The pressure maps of Atkinson et al. show that pressure gradients at depth are less than 1/3 the hydrostatic gradient, from which we conclude that no mobile liquid water is present in the reservoir. Thus, initial liquid water saturation $1-S$ should not exceed 40%. We have taken $S = 60\%$ as initial conditions (summer of 1959), while adjusting the location of the two-phase/steam interface in the course of development of the history match.

During the development of the simulation, adjustments were also made to the assumed initial conditions for summer 1959. It was necessary to relinquish some detail (local variations) in order to model successfully overall field behavior. E.g., the well VC/10 (near element E8, Figure 1) is an exceedingly strong producer ($q \approx 25$ kg/sec) with wellhead temperatures in excess of 260°C . The well VC/2 (near element C7, see Figure 1) at about 1 km distance from VC/10, has a low well head temperature of approximately 180°C . Such large variations, which translate into large pressure differences between the (two-phase) steam sources, cannot be accommodated within the mesh. It is likely that VC/10 is fed through a large fracture from depth, which is only poorly connected to the mesh, and that VC/2 is affected by shallow cold

aquifers. We connected VC/10 to a large element representing a deep boiling aquifer, and adopted smoothly varying initial conditions throughout the mesh.

Apart from the inevitable adjustment in the case of VC/10, geometry and no-flow boundary conditions were kept fixed during the simulation. This was done chiefly because modifications based on simulation alone, without independent evidence, would seem rather arbitrary and speculative. Simulation results provide indirect evidence, however, that some cold water recharge is occurring near the margins, and that some steam reaches the main well field from outside the mesh (presumably through deep fractures.)

5. Results

Our current "best" model of the Serrazzano reservoir was arrived at, in its qualitative (conceptual) and quantitative features, through a large number of simulations. Parameters had to be adjusted again and again to rectify deficits in the simulated reservoir performance. It turned out to be very difficult to sustain observed flow rates throughout the entire modeling period (1959-1975), without "overshooting" pressures in the main well field for the first few years. This difficulty gives important clues to what is happening in the field (see below).

Our model cannot resolve all of the uncertainties about parameters characterizing Serrazzano field. It remains in part speculative, and needs to be further checked and refined as more data become available. We do believe, however, that the model is plausible in view of general ideas about Serrazzano. And it appears reasonable in that it accounts for important trends and features observed in the field.

Qualitatively, the reservoir model is that of a steam cap overlying a boiling aquifer. There is dry steam in the center, near the structural high

(where the main well field is located). Pore water (i.e., two-phase zones) is confined to the margins. Water is immobile throughout. It boils in place as steam flows to the wells. The two-phase/steam interface, located at approximately -500 m (see Figure 1) acts as a nearly constant pressure boundary for the dry steam region. Gravity effects are small as only steam is mobile.

In order to sustain field production over the entire 15.5-year period modeled, we had to introduce 6 zones of different permeability (see Figure 1 and Table 3). Zone I includes the main well field. Its very high permeability is necessitated by the observation that production rates at individual wells can fluctuate appreciably without very strong pressure response. Zones II and IV are essentially regions of dry steam flow, with permeabilities adjusted such as to provide proper resistance to steam flowing from the two-phase margins toward the main well field at the center of the reservoir. Zones III and VI are essentially two-phase regions, with permeabilities such as to obtain a pattern of nearly uniform boiling and hence good pressure maintenance at the two-phase/steam interface during depletion. Zone V is the deep boiling aquifer. The time-dependence of simulated average steam pressures is shown in Figure 3. Values for the slope of pressure decline versus cumulative production (dp/dQ) deduced from this figure are given in Table 4 for the entire simulated period as well as for the post-1967 period. Average simulated pressure decline in the reservoir is somewhat slower than the value $dp/dQ = -1.9 \times 10^{-10}$ bar/kg as deduced from field data by Atkinson et al.¹⁶

Table 5 gives mass balances for the various zones, as well as for the entire reservoir. It is seen that Zones III and VI contribute roughly equal amounts to cumulative field production. Over 15 years the field loses 18.2% of the mass present on 1/1/60. Total mass reserves are approximately

1.7×10^{11} kg in 1960, and 1.4×10^{11} kg in 1975. These values are entirely consistent with Weres' estimate of an initial (pre-exploitation) mass content of 2.3×10^{11} kg, and a total cumulative steam production to date of 0.9×10^{11} kg.¹⁸

Production temperatures do not provide a meaningful test of the simulation, as much of the variation observed at the well heads is due to well-bore effects rather than reservoir processes.⁸ Simulated production temperatures are approximately constant over the 15.5 year period modeled, with variations typically around 5-10°C. This is in rough agreement with field observations, although our simulation usually does not quantitatively agree with the small observed changes.

Figure 4 compares simulated pressures for January 1960 (after 6 months of simulation) with the average pressures developed by Atkinson et al.¹⁶ We consider the overall agreement to be satisfactory. Discrepancies are most pronounced in the southeast (A-B-C-D-region) and are due to our deliberate choice of initial conditions: data from wells VC/2 and Le Prata 4 indicate that the entire region is cooler and at lower pressures than was assumed in reference 16.

Pressures obtained after 15.5 years of simulated time are compared with the January 1975 map of Atkinson et al. in Figure 5. For convenience of discussion we shall refer to the pressures as given by Atkinson et al. as "field pressures," although they are only in part backed up by actual field observations.

While the general pattern of simulated pressures does resemble the "field pressures," for the most part there is no quantitative agreement in detail. Overall, simulated pressures are somewhat high. This is particularly

evident for pressures in the two-phase region, roughly corresponding to $p > 20$ bars, in both the eastern and western margins of the field. In our model, pressures in the two-phase regions decline solely as a consequence of temperature decline due to heat loss of the rock in boiling water. As we do impose proper steam production rates, we should obtain correct overall heat loss. There are three possible reasons why for a given overall heat loss pressures in the two-phase region could decline more rapidly in the field than in our model: (i) intrusion of some colder water into depleting two-phase zones would lower temperatures, hence pressures; (ii) the actual reservoir may be somewhat thinner than our model, or the two-phase/steam interface may be at a depth greater than 500 m, so that there would be less rock mass in contact with boiling water; (iii) heat transfer from the rock to the fluid may be inhibited because some of the permeability may be due to isolated fractures rather than the rock matrix. Further investigations are required to clarify this point. Pressures are also somewhat high near the main well field (N4-A3-G4-area). This is probably not entirely due to too high pressures in the two-phase region. The 20 bar contour, which roughly coincides with the two-phase/steam interface, agrees fairly well with the field pressures in the west, without overshooting excessively in the east. Thus, in order to make simulated pressures smaller near the main well field, we would need to diminish permeability along the 1-phase flow path. This, however, would make it impossible to sustain the higher flow rates of the early 1960's. We believe that this difficulty may indicate that some of the steam supply to the main well field originates from deep fractures, rather than from that portion of the reservoir which is simulated in our present model.

Additional support for this hypothesis is provided by the peculiar depletion pattern observed during the simulation. In order to sustain the observed flow rates in the main well field, we had to fine-tune the permeability distribution carefully in the two-phase regions such as to optimize pressure maintenance at the two-phase/steam interface. This was achieved by making permeabilities in the two-phase regions rather "large," so that boiling would easily spread all the way to the hotter margins rather than being concentrated near the two-phase/steam interface. Resulting boiling rates are almost uniform throughout, and are actually increasing somewhat away from the interface toward the margins. During the entire simulation period, vapor saturations increase almost uniformly throughout the two-phase region, and the two-phase/steam interface remains stationary. These simulated results support some of the choices made with regard to initial distribution of pore water in 1959, namely, to place the two-phase/steam interface near 500 m depth, where it is believed to have been in the pre-exploitation state, and to take initial vapor saturation to be constant ($S = 60\%$) throughout the two-phase zone. Thus, the model evolves in a way which is consistent with our assumptions for initial distribution of pore water. The extent to which we had to fine-tune the permeability distribution to achieve uniform boiling (and actually going somewhat beyond) in order to sustain production may indicate that in actuality not all production is generated through boiling in the two-phase zone modeled. The results seem to suggest that an as yet undetermined amount of steam enters the main well field through fractures from depth, perhaps at a rate of a few kg/sec.

6. Conclusion

The work presented in this paper demonstrates the feasibility of field-wide distributed parameter simulations of vapor-dominated geothermal reservoirs in geologically accurate irregular geometry. The simulated model is self-consistent and shows semi-quantitative agreement with field data. We believe that the simulation provides evidence for the validity of the physical model and mathematical methods used in the simulator SHAFT79.

The simulated field behavior substantiates a conceptual model of Serrazzano reservoir as a steam cap overlying a boiling aquifer. Comparison with actual field behavior suggests the presence of cold water intrusion and/or incomplete heat transfer due to fractures at the margins, and significant upflow of steam from depth through fractures. Further work is needed to evaluate these processes quantitatively.

Our numerical model of Serrazzano reservoir, while open to further refinement, is expected to be useful for studies of cold water injection.

Future work will be directed at (i) extrapolating production beyond 1975 and comparing flow rate predictions with field data; (ii) conducting sensitivity studies to determine ranges of parameters compatible with observed field behavior; and (iii) extrapolating field performance beyond 1980, including alternative scenarios for injection of cold water.

Nomenclature

C_R	specific heat of rock, $J/^\circ C \text{ kg}$
H	thickness of reservoir, m
K_R	thermal conductivity of rock, $W/m^\circ C$
k	absolute permeability, milliDarcy ($\approx 10^{-15} m^2$)
k_{liquid}	relative permeability of liquid, fraction
k_{steam}	relative permeability of steam, fraction
p	pressure, Pascal or bar ($\equiv 10^5$ Pascal)
Q	fluid production, kg
q	rate of fluid production, kg/s
r	parameter for relative permeability functions, dimensionless
S	volumetric vapor saturation, fraction
T	temperature, $^\circ C$
t	time, s
ρ_R	rock density, kg/m^3
ϕ	porosity, dimensionless

Table 5 : Simulated Mass Balances

XBL 787-9570

Fig. 2. Serrazzano mesh in rotated perspective views.

SERRAZZANO RESERVOIR - AVERAGE PRESSURES

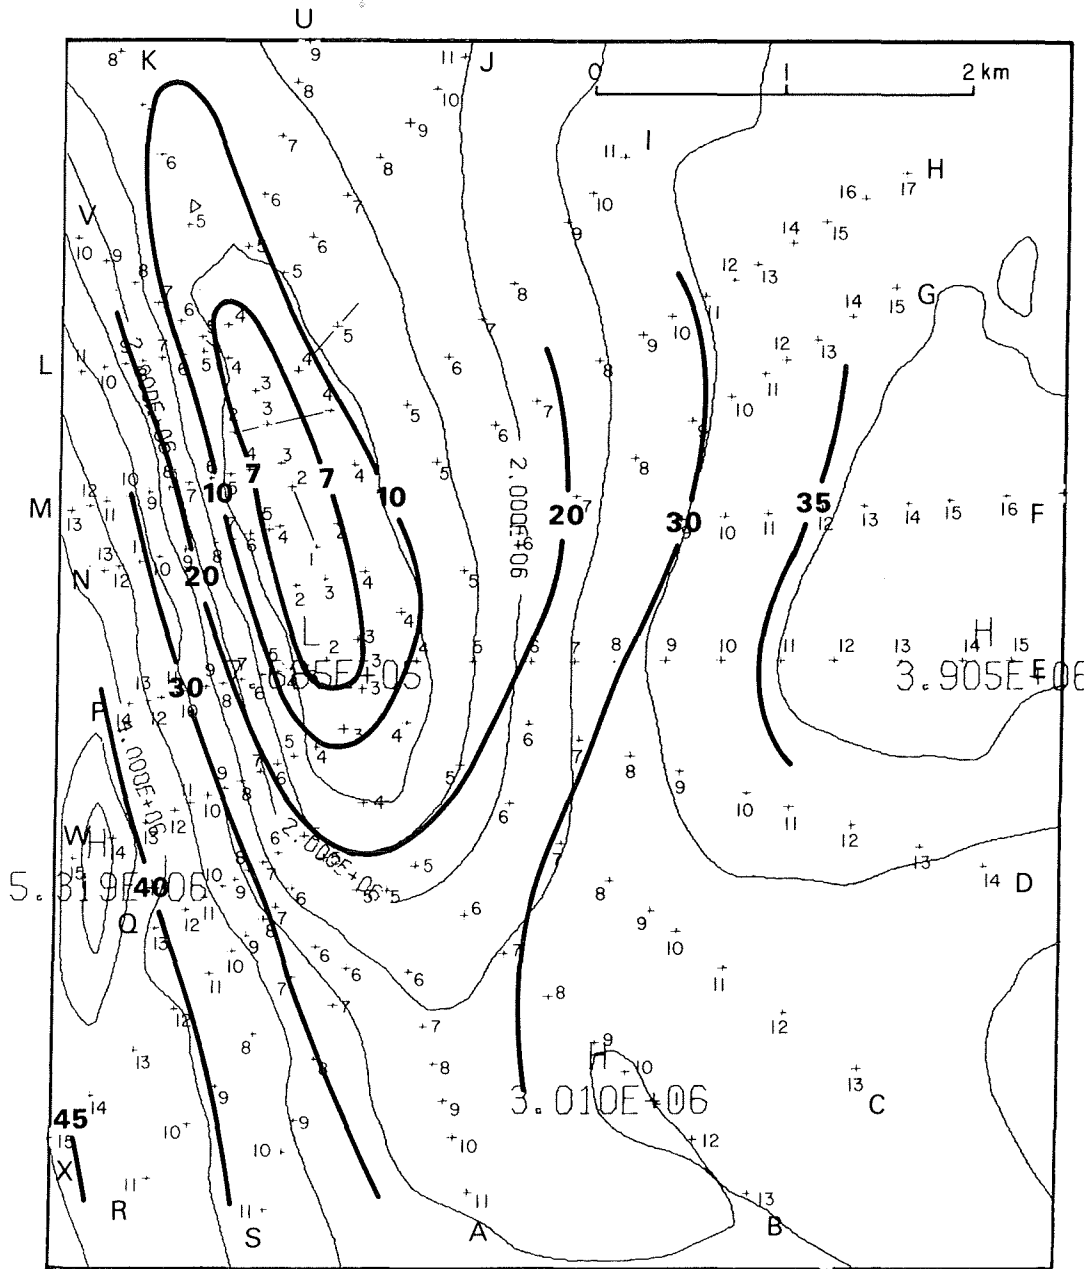

Fig. 3. Simulated average pressures.

XBL 807-1402

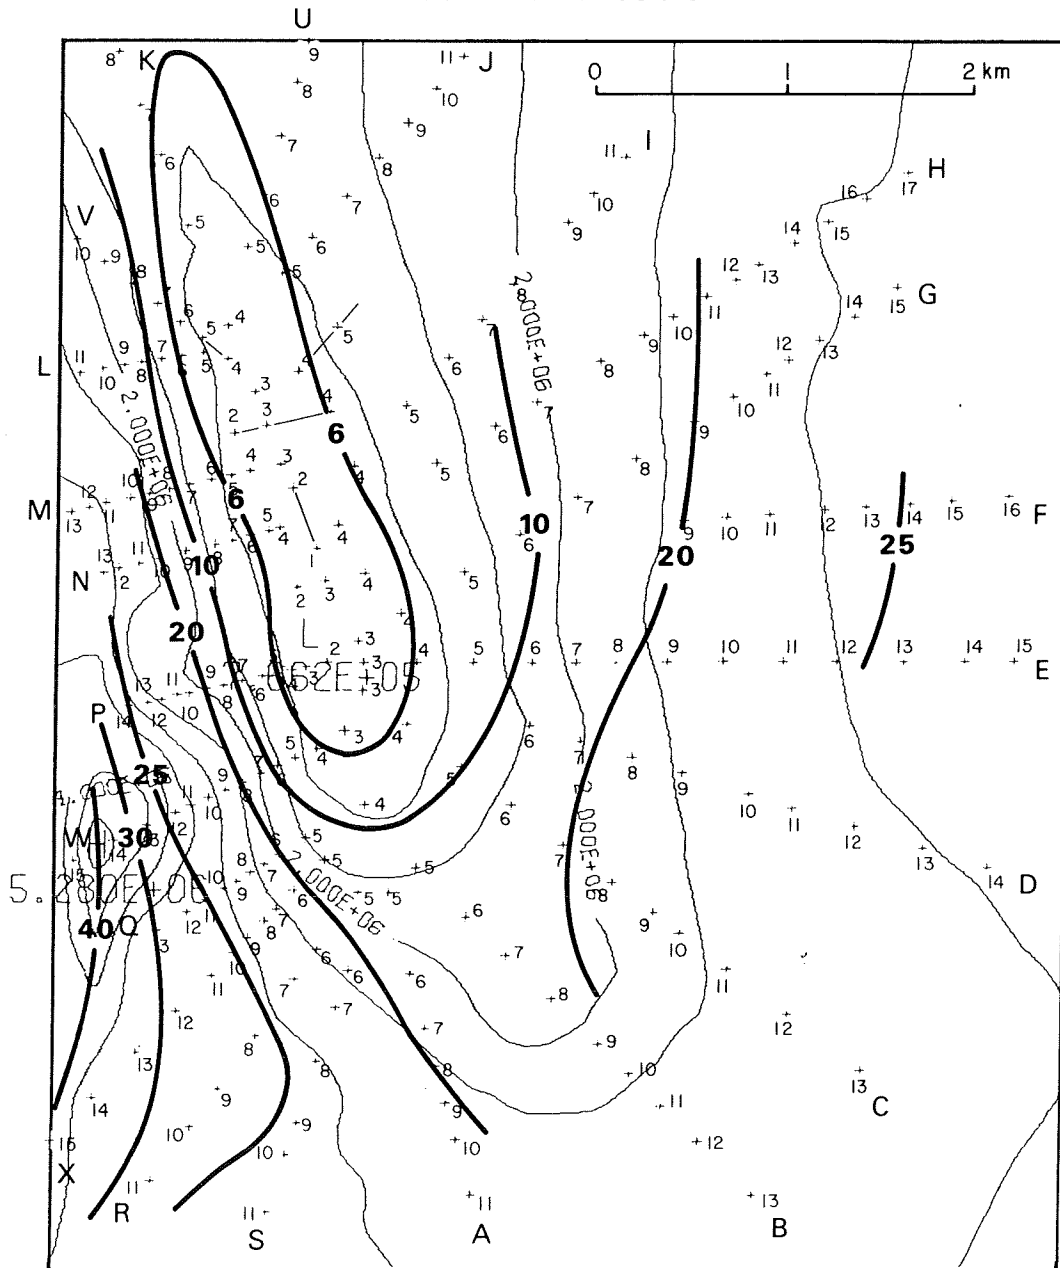

JANUARY 1960

XBL 807-1401A

Fig. 4. Pressure distribution for January 1960. The thick contours are based on field observations (units: bars), whereas the thin contours are simulated results (units: Pascals). The simulated results refer to the lowest layer of the reservoir model. Simulated vertical pressure variations are small (≈ 1 bar). Pressure increments between contour lines are 5×10^5 Pascal \equiv 5 bar.

JANUARY 1975

XBL 807-1401B

Fig. 5. Pressure distribution for January 1975.
