CONCLUSIONS

1. Analyses of drilling data and the chemistry of samples collected by Union Oil at their wells #42-7 and #31-33 at Cove Fort show that certain irregularities in the data can be explained as the results of (a) sample contamination by drilling and b) corrosion control additives. Semi-quantitative subtraction of these effects shows that the Na-Cl reservoir fluids tapped by these wells are probably more homogeneous than previously thought. Ratios of Na/K and Na/Cl are the same in both wells.
2. The principal difference between fluids from wells #42-7 and #31-33 is that #31-33 is higher overall in salinity than #42-7.
3. The top of the reservoir tapped by #42-7 has anomalously high K which remains unresolved. Release of K by alteration of feldspars to clay minerals or a source of K in evaporite deposits seems the most likely explanation.
4. Dolomites penetrated below 4,800 feet in well #31-33 contain an anomalously dilute mixed cation-mixed anion recharge water which circulates beneath the thermal reservoir above. There is weak evidence that dilute waters also enter #42-7, below about 6,000 feet.
5. SiO₂ concentrations suggest that in well #42-7 either quartz or chalcedony is nearly in equilibrium with surrounding rocks. The SiO₂ data for well #31-33 are suspect because of a discrepancy between diluted and undiluted samples. Samples diluted at the time of collection indicate oversaturation with both quartz and chalcedony, which in turn implies that the fluid is mixed or that it has migrated from a hotter source area.
6. The cation geothermometer may not be applicable to these fluids due to scarcity of feldspars in the reservoir rocks. Cation temperatures are about 210-250°C without, and 175-235°C with Mg corrections. These could reflect rock-water interaction in parts of the deep system(s) not penetrated by the wells, where feldspars are more abundant and temperatures higher.
7. This is tentative, but the cation and silica results together encourage the possibility of finding temperatures above the maximum 180°C in #42-7.
8. Shallow well and spring waters from the Cove Fort area are all relatively dilute and lack distinctive signatures which might relate them to the deep system.

INTRODUCTION

In 1978 and 1979 Union Oil Company drilled three exploration wells at Cove Fort from which hydrochemical data were obtained. This paper presents conclusions from a review of those data and of Union's interpretations of their significance. The results of shallow groundwater geochemical surveys of the surrounding area have also been examined. The work has been done at the request of Dean Pilkington under a general consulting agreement between GeothermEx, Inc. and AMAX Exploration, Inc. for the provision of geochemical services.

CABLE ADDRESS: GEOTHERMEX

BACKGROUND

The only surface manifestations of thermal activity at Cove Fort are acid-sulfate springs at Sulphurdale, which almost certainly are heated by steam rising from depth. The warmest is 40°C.

Ash and others (1979) summarize the results of the Union drilling as follows. The wells in question are #42-7, #31-33, #14-29, and Forminco #1 (a dry hole).

"The wells penetrated an underpressured, highly fractured, moderate to low temperature (178°C to 93°C), highly permeable geothermal reservoir consisting of contact metamorphic and sedimentary carbonate rock in a geologically complex area. The lack of production was due to low temperature and low pressure which together with problems of toxic H₂S gas, lost circulation and fractured and unstable formations, lead to abandonment of the project.

The geochemical data is complex. The wide variety of water, ranging from 1,320 ppm TDS to 10,000 ppm TDS was unexpected in the highly permeable reservoir that was thought to be well mixed and geochemically similar throughout the prospect.

The four wells penetrated a variable thickness of surface volcanics of mid-Tertiary age (200 to over 2,000 feet) which lies with angular unconformity over highly faulted and folded Lower Mesozoic and Upper Paleozoic sedimentary rocks. Superimposed over a portion of this framework is an aureole of contact metamorphism and mineralization related to a Mid-Tertiary intrusive event.

Static fluid levels in the wells are between 1,200 and 1,400 feet below the surface. Very high temperature gradients (13 to 16°F/100 feet) are present from the surface to the static water level in the reservoir. Below the top of the reservoir, the temperature profiles become nearly isothermal in the highly fractured and permeable reservoir. These isothermal sections are 300° to 310°F (150°-155°C) in the #42-7 well, 270°-275°F (130°-135°C) in the #31-33 well, and 190° to 195°F (85°-90°C) (not stable) in the #14-29 well.

[Two month's post-completion the isothermal section in #42-17 had disappeared, and the well increased from 306°F (152°C) at 2,000 feet to 332°F (167°C) at about 6,000 to 6,900 feet.] The maximum temperature measured in the prospect was 354°F (179°C) at 7,320

CABLE ADDRESS: GEOTHERMEX

feet in the #42-7 well. The area around the #42-7 well appears to be near the source of the geothermal anomaly, as defined by the deep drilling. The rapid termination of the shallow-well temperature anomaly east, south and west of the #42-7 well leave little room for the presence of higher reservoir temperatures, considering the highly convective nature of the reservoir."

All four wells were very expensive to drill due to lost circulation and corrosion problems.

RESULTS

All available hydrochemical data for major and minor dissolved species and most data for trace elements are shown uniformly tabulated and processed in tables 1-3. This includes approximately 20 shallow, cool ground water sources around Cove Fort and from the edge of the Belknap Caldera to the southeast. The acid-sulfate thermal springs at Sulphurdale are not listed. All data sources appear in the Bibliography.

Quality and Interpretation of Analytical Data

Most of the deep test samples show good ionic balances (table 2, column DIF), but three of the analyses do not. Samples 1.04 and 1.07 have large relative excesses of cations which appear to be due to failure to report carbonate. Errors in Na and SO_4 are also possible. The ionic imbalance of 1.15 is certainly due to incorrectly reported SO_4 . Sample 1.08 has a reasonable balance, but a ratio of HCO_3 to CO_3 which is too low given its pH.

Most of the dilute, cool recharge samples are poorly balanced. The cause or causes of this have not been explored because the background information which they provide for contrast with thermal fluids is not adversely affected.

The SiO_2 data from well #31-33 are suspect. Analyses of samples treated by dilution at the time of collection (table 1, column Rd- SiO_2) indicate that the undiluted samples (Ru- SiO_2) should be at least saturated with amorphous SiO_2 at room temperature (a minimum of about 110 mg/l SiO_2). Reported values are greatly below saturation and place into doubt the quality of the SiO_2 data from both the undiluted and the diluted samples. SiO_2 analyses (molybdate technique) are also subject to interference by iron, which is high in some samples due to corrosion.

The thermal waters are all of Na-Cl composition, in spite of variable salinity. The shallow groundwaters are dilute mixed cation-bicarbonate types.

Wells #42-7 and #31-33 were sampled at the flow line repeatedly as water was made during drilling (figures 1 and 2). Resulting analyses show variations in composition which are initially difficult to interpret because: (a) the formation water composition may shift in response to boiling and degassing as it is aerated and as it mixes with injected

(415) 527-9876

CABLE ADDRESS: GEOTHERMEX

drilling water; (b) sump water was pumped down-hole during aerated drilling, and occasionally injected in large slugs to clear the sump; (c) control of drill pipe and casing corrosion was practiced by injecting certain chemicals; (d) only occasional samples for determination of SiO_2 were diluted when collected; and (e) there is no evidence that any sample for cation determination was treated with acid, which should be done to prevent loss of calcium. The effects of these variables can, and to some extent tentatively, be subtracted from the initial results.

The Union Technical Report on well #42-7 indicates that flow-line samples were usually collected at the end of aerated drilling cycles, to minimize contamination by large injection slugs. There was corrosion control below 3,750 feet by injecting variable amounts of water soluble anime, NaOH, ammonia, organic phosphonate, Na_2SO_3 and NaNO_2 . Data on corrosion control are sketchy, but rough data on the added NaOH suggest that 10% to 20% of the Na in the flow line samples may have been contributed by the injected NaOH. Na is much more variable from sample to sample than is K, either because there are real variations in the formation fluid, analytical errors, or variable contamination (figures 3, 4). There is a strong correlation between Na and total alkalinity, which includes hydroxide ion (OH^-) and it appears that some samples are either (a) mixtures of Na-Cl and Na- HCO_3 formation waters or (b) Na-Cl formation water mixed with injected NaOH (figure 1a, note samples 1.04 and 1.07). Contamination by injected NaOH seems more likely, particularly because the strong variations in Na and alkalinity are not accompanied by shifts in SO_4 and Cl.

SiO_2 measured in undiluted samples shows a strong correlation with pH (figure 5), either because injected sump water with high pH also had dissolved high SiO_2 , because samples with higher pH tended to loose less SiO_2 during storage prior to analysis, or both.

Four flow line samples collected during aerated water drilling are available from well #31-33. It is reported that the samples were collected during cycles of drilling when there were substantial drilling returns with relatively high temperatures and low pH compared to the injected water. A fifth sample (2.05) was bailed from near TD after total salinity dropped suddenly and drastically near 4,800 feet from about 10,000 mg/l down to 1,300 mg/l. Permeable dolomite was entered at 4,800 feet beneath a sequence of sandstones and siltstones of low porosity.

Corrosion control was practiced below 2,019 feet, initially by injection of NH_4OH and phosphonate, and below 3,728 feet with substantial NaNO_2 . It is concluded in the Union Oil Technical Report that the sample from 4,170 feet (2.04) is probably the most representative of the reservoir fluid above 4,800 feet, as it has the highest salinity and so is presumably

GeothermEx, Inc.

(415) 527-9876

CABLE ADDRESS: GEOTHERMEX

less diluted by injected fluid than previous samples (2.01-2.03). However, a consideration of Na, Cl, pH and sketchy corrosion control data shows that this sample may have been the most heavily contaminated by NaOH. The Cl, Li and F in 2.04 show only a 10%-15% increase over shallower samples, whereas Na and TDS increase by 50% and 30%, respectively. Considering this, it seems that the 4,170-foot sample is possibly contaminated by NaOH (and NaNO_2 ?) and not necessarily more "representative" than the others.

Figures 6 and 7 have been developed from figures 1 and 2, to show concentrations of various species at the flowline versus depth, following elimination of the effects of suspected contamination discussed above, and slight smoothing of the curve for each specie. The curves are still approximations. There probably remains some effect of sample dilution by make-up water from the sump, but since most of the sump water was produced reservoir fluid this effect may have been small. The low salinity of sample 1.13 (7,607 feet) was due to one-day use of injection water with salinity of less than 1,000 mg/l prior to sample collection.

The curves show that the reservoir penetrated by well #42-7 is probably fairly homogeneous, except for anomalously high K at the very top. This K may have its source in evaporites or perhaps breakdown of the feldspars to form clay minerals. The decrease in salinity below about 5,560 feet is believed by Union to be caused by an increased flow of lower-salinity water into the borehole after porous wollastonite marble zones were drilled at 6,080 feet and 6,170 feet. The source and composition of this dilute water is uncertain, but it may be similar to the low salinity water found in dolomite penetrated by well #31-33 below 4,800 feet.

The reservoir penetrated by #31-33 above 4,800 feet is also fairly homogeneous, and differs from #42-7 principally in having a higher overall salinity of Na, K and Cl (note figures 3 and 4). If the reservoirs of the two wells are freely connected at depth, this may mean that #31-33 more closely represents the deep source.

Variations in SO_4 and alkalinity or HCO_3 are different in each well and contrast with the similar Na-K and Na-Cl ratios. Possible causes for variations are: (a) mixing of Na- SO_4 and Na- HCO_3 waters with Na-Cl waters; (b) shifts in equilibration of CaSO_4 and CaCO_3 with changes in temperature and Pco_2 in different parts of the reservoir(s); and (c) contamination by corrosion control additives which include NaOH and NaSO_3 . Oxidation of reservoir sulfide (H_2S) to H_2SO_4 in samples may also have occurred, but the amount of H_2S available is unlikely to fully explain the variations in SO_4 . The flowline samples of #42-7 have much higher alkalinity than does the flow test sample (1.15) which was collected following completion of drilling. This suggests that alkalinity of the flow line, as

(415) 527-9876
CABLE ADDRESS: GEOTHERMEX

represented on figure 6, may still include a large effect of contamination or some other alteration process.

Ca is not shown on figures 6 and 7 because of uncertainty about the reported data (see discussion of data quality). If its variability is due to loss of Ca from some samples prior to analysis, it may be assumed that Ca is about 40 to 70 mg/l in the reservoir of #42-7, and 60 to perhaps 200 mg/l in #31-33.

Geothermometry

Using the Na and K values of figure 6 and Ca ranging from 40 to 70 mg/l at each depth, the flowline chemistry of well #42-7 has the following cation temperatures:

<u>Depth, feet</u>	<u>T°C, NaK-Ca</u>	<u>T°C, NaKCa-Mg*</u>
3,000	260-270	230 <u>+ 5</u>
4,000	235-240	200 <u>+ 5</u>
5,000	230-235	200 <u>+ 5</u>
6,000	215-225	185 <u>+ 5</u>
7,000	210-215	175 <u>+ 5</u>
Flow Test (1.15)	237	195

*Calculated for flowline samples using Mg = 6.3, the average of samples 1.01-1.14 except 1.04, 1.07 and 1.08.

These compare with post-completion measurements in the reservoir of 150°-170°C, and a one-time maximum of 179°C at 7,320 feet.

Using the Na and K values of figure 7 and Ca ranging from 60 to 200 mg/l at each depth, the flow line chemistry of well #31-33 has the following cation temperatures:

GeothermEx, Inc.

SUITE 201
5221 CENTRAL AVENUE
RICHMOND, CALIFORNIA 94804

(415) 527-9876

CABLE ADDRESS: GEOTHERMEX

<u>Depth, feet</u>	<u>T°C, NaK-Ca</u>	<u>T°C, NaKCa-Mg*</u>
2,500	245-260	230 <u>+ 5</u>
3,000	250-265	235 <u>+ 5</u>
4,000	240-255	235 <u>+ 5</u>

*Calculated for flowline samples using Mg = 7.0, the average of samples 2.01-2.04. With Mg = 14, the corrected temperatures drop by about 30°C.

These estimates compare with measured temperatures of 130-135°C in the isothermal section of the well.

Two qualifications to the Na-K-Ca geothermometer must be observed. First, when cation temperature estimates are compared with known reservoir temperatures (as from well logs) at about 200-250°C, the chemical temperature is rarely off by more than 20°C, but it may occasionally be as much as 50°C too high. This means that the estimates for well #42-7 are generally within the limit of maximum error of the geothermometer, but beyond the limit of most probable error. Second, the cation geothermometer is based upon water-rock systems which include feldspar minerals, which may be scarce in the sections penetrated by the Cove Fort wells, particularly #42-7. The applicability of the geothermometer in carbonate and quartz sandstone reservoirs is very questionable. This means that the cation temperatures may be meaningful only if they represent water-rock interaction in other, possibly deeper parts of the systems, not penetrated by drilling, where feldspars are present. If this is the case, temperatures as high as about 230°C can be expected. Hotter fluids may be cooling and migrating laterally to the top of the section penetrated by well #42-7, and then circulating downwards, possibly cooling very slightly or mixing with more dilute components. Evidence for lateral migration of somewhat cooler, more dilute waters into deeper parts of these systems has been cited above. Decreasing cation temperatures with depth in #42-7 may reflect this mixing, or an incomplete chemical re-equilibration process.

Data for SiO₂ are somewhat irregular and spotty, and the quality of measurements from well #31-33 is uncertain. Nevertheless, the maximum estimates of the quartz and chalcedony geothermometers applied to samples

GeothermEx, Inc.

SUITE 201
5221 CENTRAL AVENUE
RICHMOND, CALIFORNIA 94804

(415) 527-9876
CABLE ADDRESS: GEOTHERMEX

diluted at the time of collection are in fair agreement with the temperatures measured in well #42-7, whereas in #31-33 oversaturation is indicated:

<u>Well</u>	<u>T°C, SiO₂</u>		<u>Measured in reservoir</u>
	<u>Quartz</u>	<u>Chalcedony</u>	
#42-7 2,000 feet-TD	175-190	165-170	150-170 (to 179°C)?
#31-33 2,000-4,800 feet	185-195	165-175	130-135
below 4,800 feet	158	133	115 at TD

At temperatures below about 200°C, and in sedimentary rocks, silica may be controlled by either quartz or chalcedony. A decisive choice between the two geothermometers is not possible. In either case, it appears that silica has more closely equilibrated to reservoir temperatures at the depths tapped by the two wells than have the cations.

The single sample from well #14-29 (sample 3.01) has similar Cl to the #42-7 reservoir fluid, but much higher Ca and Mg and lower Na and K. This well was drilled to only 2,620 feet. The fluid sampled probably has migrated from a hotter part of the reservoir, reacting with rocks as it cools, and perhaps mixing with Ca-Mg-HCO₃ recharge. The chalcedony and cation temperatures agree roughly with a measured 85-90°C (not stable).

Column headings (some may not appear):

N = sample number for tabulation

NAME = Well Number (N = 1.01 to 3.01) or sample Number (N = 4.00 to 23.00)
Samples N = 4.00-16.00 are from AMAX Geochem. files, N = 17.00-23.00
from McHugh and others (1980)

DATE = sample collection date, yr-mo-day

TIME = time of collection

DEPTH = drilling depth at time of collection

TYPE: FL = from flow line during aerated water drilling, for N = 1.01 to 3.01

B = bailed, for N = 1.01 to 3.01

SU = sump or suction pit, for N = 1.01 to 3.01

FT = flow test, for N = 1.01 to 3.01

SP = spring, for N = 4.00 to 23.00

WE = well, for N = 4.00 to 23.00

SS = spring or surface, for N = 4.00 to 23.00

PHL = pH

CA ... CL, F, MN = ionic species, concentrations in mg/l (NO3 as N)

SI02 = silica in mg/l. Ru = measured in untreated sample. Rd = measured in
sample diluted at time of collection

TDSM = total dissolved solids reported by data source.

TDSS = total dissolved solids by summation of CA through CL, plus SI02

EC = conductivity at 25°C, micromhos/cm

B = atomic boron in mg/l

FET = total iron

FEF = filtrable iron

COM = Comment

Note = All 9's or blank means no data are available, does not apply,
or insufficient data are available to permit calculation.
0.0 means below detection limit of analysis.

Detection limits:

For N = 1.01-3.01	Mg < 1.0	For N = 4.00-16.00: no limits given
	CD < 0.001

TABLE 2. Analysis in milliequivalents, calculated conductivity, ionic balance, ionic ratios, Cove Fort, Utah

Column headings:

N = sample number for tabulation
CA ... CL, F = concentration in milliequivalents/liter
B = concentration of boron in millimoles/liter
ECOBS = measured conductivity, micromhos/cm at 25°C (laboratory)
ECCAL = calculated conductivity
OBCA = ECOBS/ECCAL
SCAT = sum of cations CA ... K (meq/l)
SAN = sum of anions HCO₃ ... CL, F, (meq/l)
SUM = SCAT + SAN
DIF = ((SCAT - SAN)/(SCAT + SAN)) x 100
CAF = CA/SCAT
MGF = MG/SCAT
NKF = (NA + K)/SCAT
HCF = (HCO₃ + CO₃)/(HCO₃ + CO₃ + SO₄ + CL)
SOF = SO₄/(HCO₃ + CO₃ + SO₄ + CL)
CLF = CL/(HCO₃ + CO₃ + SO₄ + CL)
BCL = (B/CL) x 100
I = Ionic strength (calculated using molar concentrations)
NACA = Na/Ca
NAK = Na/K
FCL = (F/Cl)x100

Note: All 9's means no data are available, or insufficient data to permit calculation.
0.0 means below detection limit of analysis

TABLE 3. Chemical geothermometers,
Cove Fort, Utah

Column headings:

N = sample number for tabulation

TC = temperature in degrees Centigrade

Silica geothermometers (0-250°C; SiO₂ in ppm)

OTZC = quartz, conductive cooling	T°C = (1309/(5.19-log SiO ₂))-273.15
QTZA = quartz, adiabatic cooling	T°C = (1522/(5.75-log SiO ₂))-273.15
CHAL = chalcedony, conductive cooling	T°C = (1032/(4.69-log SiO ₂))-273.15
AMOR = amorphous silica, conductive cooling	T°C = (731/(4.52-log SiO ₂))-273.15

NaKCa geothermometer (4-340°C; Na, K, Ca in moles/liter)

SQ = (Ca)^{1/2}/Na

B43 = temperature for B = 4/3

B13 = temperature for B = 1/3

NKC = NaKCa temperature =
B43 for SQ>1 and T°C<100
B13 for SQ<1 or B43>100

$$T^{\circ}C = \left(\frac{1647}{\log \left(\frac{Na}{K} \right) + B \log (SQ) + 2.24} \right) - 273.15$$

Mg-corrected NaKCa geothermometer

R = (Mg/(Mg+Ca+K)) x 100, units in equivalents/l.

DMG = Mg-correction, T°C, for 1<R<50 and NKCa>70°C. If R>50 assume that the underground temperature is relatively cool. If R<1 correction is negligible (Ref. 1).

CMG = Mg-corrected NaKCa temperature T°C = NKCa-DMG (for DMG>0).

PCO₂-corrected NaKCa geothermometer

PH = sample pH, field measurement if available.

HCO₃ = HCO₃, meq/l

PCO₂ = PCO₂ at sample temperature, -log PCO₂ = pH -log (HCO₃)-7.689
-4.22(10⁻³)T°C - 3.54(10⁻⁵(T°C)²

PCC = PCO₂-corrected NaKCa temperature.

$$T^{\circ}C = \left(\frac{1647}{\log \left(\frac{Na}{K} \right) + \frac{4}{3} \log (SQ) + 3.6 + .253 \log PCO_2} \right) - 273.15$$

Applicable only to water equilibrated at less than 75°C.

Table 3 (continued)

NaK geothermometer (>150°C; Na, K in ppm)

NAK = NaK temperature $T^{\circ}\text{C} = \frac{1217}{\log(\text{Na}/\text{K})+1.483} - 273.15$

Note: All 9's means no data or geothermometer inapplicable.

RESOURCE CHARACTERISTICS

- I. Roosevelt Hot Springs 379 - 546
Estimated Reservoir Temperature: 193-282°C
Estimated Reservoir Depths: 800-5000+ feet
Basic Geology: Fractured igneous rock; tertiary granite
and Precambrian gneisses.
- II. Cove Fort - Sulphurdale
Estimated Reservoir Temperature: 211°C (Na-K-Ca @ 5560');
179°C measured maximum
Estimated Reservoir Depths: 2000-7000 feet
Basic Geology: Fractured sandstone, dolomite and marble.
- III. Thermo Hot Springs
Estimated Reservoir Temperature: 130°C-170°C
Estimated Reservoir Depths: Not known
Basic Geology: Not known-probably fractured igneous or
deep circulation on Basin and Range faults.
